AWS Documentation

Release 20.0w

AdaCore

Jul 12, 2019

CONTENTS

INTRODUCTION

AWS stand for *Ada Web Server*. It is an Ada implementation of the *HTTP/1.1* protocol as defined in the RFC-2616 from June 1999.

The goal is not to build a full Web server but more to make it possible to use a Web browser (like Internet Explorer, or Netscape Navigator) to control an Ada application. As we'll see later it is also possible to have two Ada programs exchange informations via the *HTTP* protocol. This is possible as *AWS* also implement the client side of the HTTP protocol.

Moreover with this library it is possible to have more than one server in a single application. It is then possible to export different kind of services by using different *HTTP* ports, or to have different ports for different services priority. Client which must be served with a very high priority can be assigned a specific port for example.

As designed, *AWS* big difference with a standard *CGI* server is that there is only one executable. A *CGI* server has one executable for each request or so, this becomes a pain to build and to distribute when the project gets bigger. We will also see that it is easier with *AWS* to deal with session data.

AWS support also *HTTPS* (secure *HTTP*) using *SSL*. This is based on either *OpenSSL* or *GNUTLS* two Open Source SSL implementations.

Major supported features are:

- HTTP implementation

- HTTPS (Secure HTTP) implementation based on SSLv3

- Template Web pages (separate the code and the design)

- Web Services - SOAP based

- WSDL support (generate stub/skeleton from WSDL documents)

- Basic and Digest authentication

- Transparent session handling (server side)

- HTTP state management (client side cookies)

- File upload

- Server push

- SMTP / POP (client API)

- LDAP (client API)

- Embedded resources (full self dependant Web server)

- Complete client API, including HTTPS

- Web server activity log

BUILDING AWS

2.1 Requirements

AWS has been mainly developed with *GNAT* on Windows. It is built and tested regularly on *GNU/Linux* and *Solaris*, it should be fairly portable across platforms. To build *AWS* you need:

- GNU/Ada (GNAT compiler) ;

  Obviously an Ada compiler is mandatory. Only GNAT is tested, the code should be fairly portable but has never been tested on another compiler. See INSTALL file distributed with AWS for specific versions supported.

- OpenSSL (**optional**) ;

  OpenSSL is an Open Source toolkit implementing the *Secure Sockets Layer* (SSL v2 and v3 and TLS 1.1, 1.2) and much more. It is possible to download the OpenSSL source distribution from *http://www.openssl.org <http://www.openssl.org>* and build it. A Windows binary distribution may also be downloaded there.

- LibreSSL (**optional**) ;

  LibreSSL is an Open Source toolkit implementing the *Secure Sockets Layer* which is fully compatible with OpenSSL. It is possible to download the LibreSSL source distribution from *https://www.libressl.org/>* and build it.

- GNUTLS (**optional**) ;

  GNUTLS is an Open Source toolkit implementing the *Secure Sockets Layer* (SSL v3 and TLS 1.1, 1.2) and much more. It is necessary to install the developers libraries to use it in AWS.

- OpenLDAP (**optional**) ;

  OpenLDAP is an Open Source toolkit implementing the *Lightweight Directory Access Protocol*. If you want to use the *AWS/LDAP* API on UNIX based systems, you need to install properly the *OpenLDAP* package. On Windows you don't need to install it as the `libldap.a` library will be built by *AWS* and will use the standard Windows *LDAP DLL* `wldap32.dll`.

  You can download OpenLDAP from *http://www.openldap.org <http://www.openldap.org>*.

2.2 AWS.Net.Std

This package is the standard (non-SSL) socket implementation. It exists different implementations of this package:

GNAT Version based on *GNAT.Sockets* from GNAT version 20 and later with IPv6 support. This is the **default implementation** used.

IPv6 Compartible with GNAT before version 20 socket implementation with IPv6 support:

```
$ make setup NETLIB=ipv6
```

IPv4 Compartible with GNAT before version 20 socket implementation based on GNAT.Sockets package without IPv6 support:

```
$ make setup NETLIB=ipv4
```

2.3 Building

Before building be sure to edit `makefile.conf`, this file contains many settings important for the build. Note that it is important to run *make setup* each time you edit this file.

When you have built and configured all external libraries you must set the *ADA_PROJECT_PATH* variable to point to the GNAT Project files for the different packages. For *XML/Ada* support, you also need to set *XMLADA* to *true* in `makefile.conf`.

At this point you can build *AWS* with:

```
$ make setup build
```

Note that some demos require that *AWS* be built with *SSL* support. If you want to activate *SSL* you must have installed the necessary developers libraries. It is possible to specify the *SSL* implementation to use with the *SOCKET* variable.

To build with *GNUTLS*:

```
$ make SOCKET=gnutls setup
$ make build
```

To build with *OpenSSL* or *LibreSSL*:

```
$ make SOCKET=openssl setup
$ make build
```

It is is possible to build *AWS* in debug mode by setting *DEBUG* make's variable:

```
$ make DEBUG=true setup build
```

Note that by default *AWS* is configured to use the *GNAT* compiler. So, if you use *GNAT* you can build *AWS* just with:

```
$ make setup build
```

2.4 Building on cross-platforms

To build for a cross platform the TARGET makefile variable must be set with the cross toolchain to be used. The value must be the triplet of the toolchain to use.

For example, to build on VxWorks:

```
$ make TARGET=powerpc-wrs-vxworks setup build
```

Note that on cross-environment one need to build the demos manually. See demos/README.

2.5 Demos

AWS comes with some ready to use demos. The demos are a good way to learn how to use *AWS*.

Here are a short description of them:

agent A program using the *AWS* client interface. This simple tool can be used to retrieve Web page content. It supports passing through a proxy with authentication and basic authentication on the Web site.

auth A simple program to test the Web Basic and Digest authentication feature.

autobahn A demo to validate the WebSocket implementation against the autobahn test suite.

cert A secure server using a Certificate Authority and validating clients with certificate. This is the highest security level possible.

com Two simples program that uses the *AWS* communication service.

dispatch A simple demo using the dispatcher facility. see *URI dispatcher*.

hello_world The famous Hello World program. This is a server that will always return a Web page saying 'Hello World!'.

hello_wsdl An hello world kind of application using a WSDL document for describing the messages format.

hotplug A simple test for the hotplug feature.

https A simple secure server enforcing TLS 1.2 protocol to be used by the Web Browser. This demo also uses a signed server's key and proper setup hand over the password to the secure layer.

interoplab A WSDL based demo that test most of the *SOAP* features.

jabber_demo A simple Jabber command line client to check the presence of a JID (Jabber ID). This uses the Jabber API, see *AWS.Jabber*.

multiple_sessions A demo of two embedded servers using different sessions.

res_demo A demo using the resource feature. This Web Server embedded a *PNG* image and an *HTML* page. The executable is self contained.

runme An example that test many *AWS* features.

soap_demo A simple client/server program to test the *SOAP* protocol.

soap_disp Like above but use a *SOAP* dispatcher.

soap_vs A client and server that implement seven *SOAP* procedures for testing purpose.

split A demo for the transient pages and page splitter *AWS*'s feature. Here a very big table is split on multiple pages. A set of links can be used to navigate to the next or previous page or to access directly to a given page.

test_ldap A simple *LDAP* demo which access a public *LDAP* server and display some information.

test_mail A simple application that send a set of *SMTP* messages with different kind of attachments.

text_input A simple demo which handle textarea and display the content.

vh_demo Two servers on the same machine... virtual hosting demo. see *Virtual host dispatcher*.

web_block A simple Web Bock based counter.

web_block_ajax As above but using also *Ajax*.

web_block_ajax_templates As above but using also the *templates2ada* tool which create a tight coupling between the web templates and the *Ada* code.

web_elements A driver to browse the Web Elements library and see some examples.

web_mail A simple Web Mail implementation that works on a *POP* mailbox.

websockets A simple WebSocket demo.

wps A very simple static Web page server based on *AWS.Services.Page_Server*. see *Static Page server*.

ws A static Web page server and push enabled server.

ws_candy A WebSocket demo using many of the WebSocket's features.

zdemo A simple demo of the Gzip content encoding feature.

For build instructions see `demos/README`.

2.6 Installing

When the build is done you must install *AWS* at a specific location. The target directory is defined with the *prefix* `makefile.conf` variable. The default value is set to the compiler root directory. Note that the previously installed version is automatically removed before installing the new one. To install:

```
$ make install
```

To install *AWS* into another directory you can either edit `makefile.conf` and set *prefix* to the directory you like to install *AWS* or just force the make *prefix* variable:

```
$ make prefix=/opt install
```

Alternatively, with *GNAT* 5.03 and above it is possible to install *AWS* into the GNAT Standard Library location. In this case *AWS* is ready-to-use as there is no need to set *ADA_PROJECT_PATH*, just set *prefix* to point to *GNAT* root directory:

```
$ make prefix=/opt/gnatpro/6.1.1 install
```

Now you are ready to use *AWS* !

USING AWS

3.1 Setting up environment

3.1.1 Using environment variables

After installing *AWS* you must set the build environment to point the compiler to the right libraries. First let's say that *AWS* has been installed in `awsroot` directory.

Following are the instructions to set the environment yourself. Note that the preferred solution is to use project files. In this case there is no manual configuration.

spec files

> The spec files are installed in `<awsroot>/include/aws`. Add this path into *ADA_INCLUDE_PATH* or put it on the command line *-aI<awsroot>/include/aws*.

libraries

> The GNAT library files (`.ali`) and the *AWS* libraries (`libaws.a`) are installed into `<awsroot>/lib/aws`. Add this path into *ADA_OBJECTS_PATH* or put it on the command line *-aO<awsroot>/lib/aws/static*. Furthermore for *gnatlink* to find the libraries you must add the following library path option on the *gnatmake* command line *-largs -L<awsroot>/lib/aws -laws*.

> Note that to build SSL applications you need to add *-lssl -lcrypto* on gnatmake's *-largs* section.

external libraries

> You must do the same thing (setting *ADA_INCLUDE_PATH* and *ADA_OBJECTS_PATH*) for all external libraries that you will be using.

3.1.2 Using GNAT Project Files

The best solution is to use the installed GNAT Project File `aws.gpr`. This is supported only for *GNAT 5.01* or above. You must have installed *XML/Ada* with project file support too.

If this is the case just set the *ADA_PROJECT_PATH* variable to point to the *AWS* and *XML/Ada* install directories. From there you just have to with the *AWS* project file in your GNAT Project file, nothing else to set:

```
with "aws";

project Simple is

  for Main use ("prog.adb");

  for Source_Dirs use ("src");
```

```
  for Object_Dir use "obj";

end Simple;
```

See the *GNAT User's Guide* for more information about GNAT Project Files.

3.2 Basic notions

AWS is not a Web Server like *IIS* or *Apache*, it is a component to embedded HTTP protocol in an application. It means that it is possible to build an application which can also answer to a standard browser like *Internet Explorer* or *Netscape Navigator*. Since *AWS* provides support client and server HTTP protocol, applications can communicate through the HTTP channel. This give a way to build distributed applications, see *AWS.Client*.

An application using *AWS* can open many *HTTP* channels. Each channel will use a specific port. For example, it is possible to embedded many *HTTP* and/or many *HTTPS* channels in the same application.

3.2.1 Building an AWS server

To build a server you must:

- declare the HTTP Web Server:

```
WS  : AWS.Server.HTTP;
```

- Start the server

  You need to start the server before using it. This is done by calling *AWS.Server.Start* (see *AWS.Server*):

```
procedure Start
  (Web_Server               : in out HTTP;
   Name                     : in     String;
   Callback                 : in     Response.Callback;
   Max_Connection           : in     Positive    := Def_Max_Connect;
   Admin_URI                : in     String      := Def_Admin_URI;
   Port                     : in     Positive    := Def_Port;
   Security                 : in     Boolean     := False;
   Session                  : in     Boolean     := False;
   Case_Sensitive_Parameters : in    Boolean     := True;
   Upload_Directory         : in     String      := Def_Upload_Dir);
--  Start the Web server. It initialize the Max_Connection connections
--  lines. Name is just a string used to identify the server. This is used
--  for example in the administrative page. Admin_URI must be set to enable
--  the administrative status page. Callback is the procedure to call for
--  each resource requested. Port is the Web server port. If Security is
--  set to True the server will use an HTTPS/SSL connection. If Session is
--  set to True the server will be able to get a status for each client
--  connected. A session ID is used for that, on the client side it is a
--  cookie. Case_Sensitive_Parameters if set to False it means that the CGI
--  parameters name will be handled without case sensitivity. Upload
--  directory point to a directory where uploaded files will be stored.
```

The procedure *Start* takes many parameters:

Web_Server

this is the Web server to start.

Name

> This is a string to identify the server. This name will be used for example in the administrative status page.

Callback

> This is the procedure to call for each requested resources. In this procedure you must handle all the possible URI that you want to support. (see below).

Max_Connection

> This is the maximum number of simultaneous connections. It means that Max_Connection client's browsers can gets answer at the same time. This parameter must be changed to match your needs. A medium Web server will certainly need something like 20 or 30 simultaneous connections.

Admin_URI

> This is a special URI recognized internally by the server. If this URI is requested the server will return the administrative page. This page is built using a specific template page (default is '**aws_status.thtml**'), see *Status page*.

> The administrative page returns many information about the server. It is possible to configure the server via two configuration files see *Configuration options*.

Port

> This is the port to use for the Web server. You can use any free port on your computer. Note that on some OS specific range could be reserved or needs specials privileges (port 80 on Linux for example).

Security

> If Security is set to True the server will use an HTTPS/SSL connection. This part uses the *OpenSSL* or *GNUTLS* library.

Session

> If Session is set to true the server will keep a session ID for each client. The client will be able to save and get variables associated with this session ID.

Case_Sensitive_Parameters

> If set to True the CGI name parameters will be handled without using the case.

Note that there is other *Start* routines which support other features. For example there is a *Start* routine which use a dispatcher routine instead of the simple callback procedure, see *AWS.Server*. And there is also the version using a *Config.Object* which is the most generic one.

- provides a callback procedure

  The callback procedure has the following prototype:

  ```
  function Service (Request : in AWS.Status.Data) return AWS.Response.Data;
  ```

  This procedure receive the request status. It is possible to retrieve information about the request through the *AWS.Status* API (see *AWS.Status.*).

  For example, to know what URI has been asked:

  ```
  URI : constant String := AWS.Status.URI (Request);

  if URI = "/whatever" then
      ...
  end if;
  ```

Then this function should return an answer using one of the constructors in *AWS.Response* (see *AWS.Response.*). For example, to return an *HTML* message:

```
AWS.Response.Build (Content_Type => "text/html",
                    Message_Body => "<p>just a demo");
```

It is also possible to return a file. For example, here is the way to return a PNG image:

```
AWS.Response.File (Content_Type => "image/png",
                   Filename     => "adains.png");
```

Note that the main procedure should exit only when the server is terminated. For this you can use the *AWS.Server.Wait* service.

A better solution is to use a template engine like Templates_Parser to build the *HTML* Web Server answer. Templates_Parser module is distributed with this version of AWS.

3.2.2 Callback procedure

The callback procedure is the user's code that will be called by the AWS component to get the right answer for the requested resource. In fact AWS just open the HTTP message, parsing the HTTP header and it builds an object of type *AWS.Status.Data*. At this point it calls the user's callback procedure, passing the object. The callback procedure must returns the right response for the requested resources. Now AWS will just build up the HTTP response message and send it back to user's browser.

But what is the resource ?

Indeed in a standard Web development a resource is either a static object - an *HTML* page, an *XML* or *XSL* document - or a *CGI* script. With *AWS* a resource is *just a string* to identify the resource, it does not represent the name of a static object or *CGI* script.

So this string is just an internal representation for the resource. The callback procedure must be implemented to handle each internal resource and return the right response.

Let's have a small example. For example we want to build a Web server that will answer 'Hello World' if we ask for the internal resource **/hello**, and must answer 'Hum...' otherwise:

```ada
with AWS.Response;
with AWS.Server;
with AWS.Status;

procedure Hello_World is

   WS : AWS.Server.HTTP;

   function HW_CB (Request : in AWS.Status.Data)
     return AWS.Response.Data
   is
      URI : constant String := AWS.Status.URI (Request);
   begin
      if URI = "/hello" then
         return AWS.Response.Build ("text/html", "<p>Hello world !");
      else
         return AWS.Response.Build ("text/html", "<p>Hum...");
      end if;
   end HW_CB;

begin
```

```
   AWS.Server.Start
      (WS, "Hello World", Callback => HW_CB'Unrestricted_Access);
   delay 30.0;
end Hello_World;
```

Now of course the resource internal name can represent a file on disk. It is not mandatory but it is possible. For example it is perfectly possible to build with *AWS* a simple page server.

As an example, let's build a simple page server. This server will returns files in the current directory. Resources internal name represent an *HTML* page or a *GIF* or *PNG* image for example. This server will return a 404 message (Web Page Not Found) if the file does not exist. Here is the callback procedure that implements such simple page server:

```
function Get (Request : in AWS.Status.Data) return AWS.Response.Data is
   URI      : constant String := AWS.Status.URI (Request);
   Filename : constant String := URI (2 .. URI'Last);
begin
   if Utils.Is_Regular_File (Filename) then
      return AWS.Response.File
              (Content_Type => AWS.MIME.Content_Type (Filename),
               Filename     => Filename);

   else
      return AWS.Response.Acknowledge
        (Messages.S404,
         "<p>Page '" & URI & "' Not found.");
   end if;
end Get;
```

3.2.3 Form parameters

Form parameters are stored into a table of key/value pair. The key is the form input tag name and the value is the content of the input field as filled by the user:

```
Enter your name

<FORM METHOD=GET ACTION=/get-form>"
<INPUT TYPE=TEXT NAME=name VALUE="<default>" size=15>
<INPUT TYPE=SUBMIT NAME=go VALUE="Ok">
</FORM>
```

Note that as explained above *Callback procedure*, the resource described in *ACTION* is just an internal string representation for the resource.

In this example there is two form parameters:

name The value is the content of this text field as filled by the client.

go The value is "Ok".

There is many functions (in *AWS.Parameters*) to retrieve the tag name or value and the number of parameters. Here are some examples:

```
function Service (Request : in AWS.Status.Data) return AWS.Response.Data is
   P : constant AWS.Parameters.List := AWS.Status.Parameters (Request);
...
```

AWS.Parameters.Get (P, "name")

Returns the value for parameter named **name**

AWS.Parameters.Get_Name (P, 1)

Returns the string "name".

AWS.Parameters.Get (P, 1)

Returns the value for parameter named **name**

AWS.Parameters.Get (P, "go")

Returns the string "Ok".

AWS.Parameters.Get_Name (P, 2)

Returns the string "go".

AWS.Parameters.Get (P, 2)

Returns the string "Ok".

Request is the *AWS* current connection status passed to the callback procedure. And *P* is the parameters list retrieved from the connection status data. For a discussion about the callback procedure see *Building an AWS server*.

3.2.4 Distribution of an AWS server

The directory containing the server program must contain the following files if you plan to use a status page see *Status page*.

aws_status.thtml

The template *HTML* file for the *AWS* status page.

aws_logo.png

The *AWS* logo displayed on the status page.

aws_up.png

The *AWS* hotplug table up arrow.

aws_down.png

The *AWS* hotplug table down arrow.

Note that these filenames are the current *AWS* default. But it is possible to change those defaults using the configuration files see *Configuration options*.

3.3 Building answers

We have already seen, in simple examples, how to build basic answers using *AWS.Response* API. In this section we present all ways to build answers from basic support to the more advanced support like the compressed memory stream response.

3.3.1 Redirection

A redirection is a way to redirect the client's browser to another URL. Client's won't notice that a redirection has occurs. As soon as the browser has received the response from the server it will retrieve the page as pointed by the redirection:

```
return Response.URL (Location => "/use-this-one");
```

3.3.2 New location for a page

User will receive a Web page saying that this page has moved and eventually pointing to the new location:

```
return Response.Moved
  (Location => "/use-this-one";
   Message  => "This page has moved, please update your reference");
```

3.3.3 Authentication required

For protected pages you need to ask user to enter a password. See *Authentication*.

3.3.4 Sending back an error message

Acknowledge can be used to send back error messages. There is many kind of status code, see *Message.Status_Code* definition. Together with the status code it is possible to pass textual error message in *Message_Body* parameter:

```
return Response.Acknowledge
  (Status_Code  => Messages.S503,
   Message_Body => "Can't connect to the database, please retry later.",
   Content_Type => MIME.Text_Plain);
```

3.3.5 Response from a string

This is the simplest way to build a response object. There is two constructors in *AWS.Response*, one based on a standard string and one for Unbounded_String:

```
return Response.Build (MIME.Text_HTML, "My answer");
```

The Build routine takes also a status code parameter to handle errors. By default this code is *Messages.S200* which is the standard HTTP status (no error encountered). The other parameter can be used to control caches. See *AWS.Response*.

3.3.6 Response from a Stream_Element_Array

This is exactly as above but the Build routine takes a *Stream_Element_Array* instead of a string.

3.3.7 Response from a file

To build a *File* response there is a single constructor named *File*. This routine is very similar to the one above except that we specify a filename as the response:

```
return Response.File (MIME.Text_HTML, "index.html");
```

Again there parameters to control the status code and cache. No check on the filename is done at this point, so if `index.html` does not exit no exception is raised. The server is responsible to check for the file and to properly send back the 404 message if necessary.

Note that this routine takes an optional parameter named *Once* that is to be used for temporary files created on the server side for the client. With *Once* set to *True* the file will be deleted by the server after sending it (this includes the case where the download is suspended).

3.3.8 Response from a stream

Sometimes it is not possible (or convenient) to build the response in memory as a string object for example. Streams can be used to workaround this. The constructor for such response is again very similar to the ones above except that instead of the data we pass an handle to a *Resources.Streams.Stream_Type* object.

The first step is to build the stream object. This is done by deriving a new type from *Resources.Streams.Stream_Type* and implementing three abstract procedures.

Read

> Must return the next chunk of data from the stream. Note that initialization if needed are to be done there during the first call to read.

End_Of_File

> Must return True when there is no more data on the stream.

Close

> Must close the stream and for example release all memory used by the implementation.

The second step is to build the response object:

```
type SQL_Stream is new Resources.Streams.Stream_Type;

Stream_Object : SQL_Stream;

procedure Read (...) is ...
function End_Of_File (...) return Boolean is ...
procedure Close (...) is

...

return Response.Stream (MIME.Text_HTML, Stream_Object);
```

Note that in some cases it is needed to create a file containing the data for the client (for example a tar.gz or a zip archive). But there is no way to properly remove this file from the file system as we really don't know when the upload is terminated when using the *AWS.Response.File* constructor. To solve this problem it is possible to use a stream as the procedure *Close* is called by the server when all data have been read. In this procedure it is trivial to do the necessary clean-up.

3.3.9 Response from a on-disk stream

An ready-to-use implementation of the stream API described above where the stream content is read from an on-disk file.

3.3.10 Response from a on-disk once stream

An ready-to-use implementation of the stream API described above where the stream content is read from an on-disk file. When the transfer is completed the file is removed from the file system.

3.3.11 Response from a memory stream

This is an implementation of the standard stream support described above. In this case the stream is in memory and built by adding data to it.

To create a memory stream just declare an object of type *AWS.Resources.Streams.Memory.Stream_Type*. When created, this memory stream is empty, using the *Streams.Memory.Append* routines it is possible to add chunk of data to it. It is of course possible to call *Append* as many times as needed. When done just return this object to the server:

```
Data : AWS.Resources.Streams.Memory.Stream_Type;

Append (Data, Translator.To_Stream_Element_Array ("First chunk"));
Append (Data, Translator.To_Stream_Element_Array ("Second chunk..."));

...

return Response.Stream (MIME.Text_HTML, Data);
```

Note that you do not have to take care of releasing the allocated memory, the default *Close* routine will do just that.

3.3.12 Response from a compressed memory stream

This is a slight variant of the standard memory stream described above. In this case the stream object must be declared as a *AWS.Resources.Streams.Memory.ZLib.Stream_Type*.

The ZLib stream object must be initialized to enable the compression and select the right parameters. This is done using the *AWS.Resources.Streams.Memory.ZLib.Deflate_Initialize* routine which takes many parameters to select the right options for the compression algorithm, all of them have good default values. When initialized the compressed stream object is used exactly as a standard stream:

```
Data : AWS.Resources.Streams.Memory.ZLib.Stream_Type;

Deflate_Initialize (Data);

Append (Data, Translator.To_Stream_Element_Array ("First chunk"));
Append (Data, Translator.To_Stream_Element_Array ("Second chunk..."));

...

return Response.Stream (MIME.Text_HTML, Data);
```

Note that there is the reverse implementation to decompress a stream. See *AWS.Resources.Streams.Memory.ZLib*. It's usage is identical.

3.3.13 Split page

AWS has a specific high level service to split a large response into a set of pages. For more information see *Split pages*.

3.3.14 Response a from pipe stream

The response sent to the server is read from the output of an external application. This kind of stream can be used to avoid writing a temporary file into the hard disk. For example it is possible to return an archive created with the *tar* tool without writing the intermediate tar achive on the disk.

3.4 Configuration options

To configure an *AWS* server it is possible to use a configuration object. This object can be set using the *AWS.Config.Set* API or initialized using a configuration file.

Configuration files are a way to configure the server without recompiling it. Each application can be configured using two configurations files:

aws.ini

> This file is parsed first and corresponds to the configuration for all AWS server runs in the same directory.

<program_name>.ini

> This file is parsed after `aws.ini`. It is possible with this initialization file to have specific settings for some servers. `program_name.ini` is looked first in the application's directory and then in the current working directory. This is only supported on platforms where *Ada.Command_Line* is implemented. So, on **VxWorks** only `aws.ini` is parsed.

Furthermore, it is possible to read a specific configuration file using the *AWS.Config.Ini.Read* routine. See *AWS.Config.Ini*.

Current supported options are:

Accept_Queue_Size (positive)

> This is the size of the queue for the incoming requests. Higher this value will be and less "*connection refused*" will be reported to the client. The default value is **64**.

Admin_Password (string)

> This is the password used to call the administrative page. The password can be generated with `aws_password` (the module name must be *admin*):

```
$ aws_password admin <password>
```

Admin_URI (string)

> This is the URI to call the administrative page. This can be used when calling *AWS.Server.Start*. The default is **<not-defined>**.

Case_Sensitive_Parameters (boolean)

> If set to *True* the *HTTP* parameters are case sensitive. The default value **TRUE**.

Certificate (string)

> Set the certificate file to be used with the secure servers. The default is **cert.pem**. A single certificate or a certificate chain is supported. The certificates must be in *PEM* format and the chain must be sorted starting with the subject's certificate, followed by intermediate CA certificates if applicable and ending at the highest level (root) CA certificate. If the file contains only a single certificate, it can be followed by a private key. In this case the Key parameter (see below) must empty.

Check_URL_Validity (boolean)

Server have to check URI for validity. For example it checks that an URL does not reference a resource above the Web root. The default is **TRUE**.

Cipher_Priorities

Values are dependent on the actual secure layer (OpenSSL or GNUTLS). It is used to specify the session's handshake algorithms and options.

Cleaner_Wait_For_Client_Timeout (duration)

Number of seconds to timeout on waiting for a client request. This is a timeout for regular cleaning task. The default is **80.0** seconds.

Cleaner_Client_Header_Timeout (duration)

Number of seconds to timeout on waiting for client header. This is a timeout for regular cleaning task. The default is **7.0** seconds.

Cleaner_Client_Data_Timeout (duration)

Number of seconds to timeout on waiting for client message body. This is a timeout for regular cleaning task. The default is **28800.0** seconds.

Cleaner_Server_Response_Timeout (duration)

Number of seconds to timeout on waiting for client to accept answer. This is a timeout for regular cleaning task. The default is **28800.0** seconds.

Config_Directory (string)

The directory in which AWS keeps some configuration parameters. The default is **.config/ada-web-srv**.

CRL_File (string)

This configuration option must point to a filename containing a CRL (Certificate Revocation List). This will make it possible to control client connecting to the server. The default values is **<not-defined>**.

Directory_Browser_Page (string)

Specify the filename for the directory browser template page. The default value is **aws_directory.thtml**.

Down_Image (string)

The name of the down arrow image to use in the status page. The default is **aws_down.png**.

Error_Log_Activated (boolean)

A boolean to enable or disable the error log. By default the error log activation is set to **FALSE**.

Error_Log_Filename_Prefix (string)

This is to set the filename prefix for the error log file. By default the error log filename prefix is the program name (without extension) followed by "_error".

Error_Log_Split_Mode [None/Each_Run/Daily/Monthly]

It indicates how to split the error logs. Each_Run means that a new log file is used each time the process is started. Daily and Monthly will use a new log file each day or month. The default is **NONE**.

Exchange_Certificate (boolean)

If set to True it means that the client will be asked to send its certificate to the server. The default value is **FALSE**.

Certificate_Required (boolean)

If set to True the server will reject all SSL connections if the client did not provide a certificate (be it valid or not). The *Exchange_Certificate* option must be set in this case. The default value is **FALSE**.

Force_Wait_For_Client_Timeout (duration)

Number of seconds to timeout on waiting for a client request. This is a timeout for urgent request when resources are missing. The default is **2.0** seconds.

Force_Client_Header_Timeout (duration)

Number of seconds to timeout on waiting for client header. This is a timeout for urgent request when resources are missing. The default is **2.0** seconds.

Force_Client_Data_Timeout (duration)

Number of seconds to timeout on waiting for client message body. This is a timeout for urgent request when resources are missing. The default is **10800.0** seconds.

Force_Server_Response_Timeout (duration)

Number of seconds to timeout on waiting for client to accept answer. This is a timeout for urgent request when resources are missing. The default is **10800.0** seconds.

Free_Slots_Keep_Alive_Limit (positive)

This is the minimum number of remaining free slots to enable keep-alive HTTP connections. For heavy-loaded HTTP servers, the Max_Connection parameter should be big enough, and Free_Slots_Keep_Alive_Limit should be about 1-10% of the Max_Connection parameter depending on the duration of the average server response. Longer is the average time to send back a response bigger Free_Slots_Keep_Alive_Limit should be. The default is **1**.

Hotplug_Port (positive)

This is the hotplug communication port needed to register and un-register an hotplug module. The default value is **8888**.

Key (string)

Set the RSA key file to be used with the secure servers. The default file is **<not-defined>**.

Line_Stack_Size (positive)

The HTTP lines stack size. The stack size must be adjusted for each applications depending on the use of the stack done by the callback procedures. The default is **1376256**.

Log_Activated (boolean)

A boolean to enable or disable the standard log. By default the standard log activation is set to **FALSE**.

Log_Extended_Fields (string list)

Comma separated list of the extended log field names. If this parameter is empty, the HTTP log would be in the apache compartible format, otherwise log file would be in Extended format. For more information see *Server Log*.

Log_File_Directory (string)

This is to set the directory where log file must be written. This parameter will be used automatically by *AWS.Log* if logging facility is enabled. By default log files are written in the current directory. The default is **./**.

Log_Filename_Prefix (string)

This is to set the filename prefix for the log file. By default the log filename prefix is the program name (without extension).

Log_Split_Mode [None/Each_Run/Daily/Monthly]

It indicates how to split the logs. Each_Run means that a new log file is used each time the process is started. Daily and Monthly will use a new log file each day or month. The default is **NONE**.

Logo_Image (string).

The name of the logo image to use in the status page. The default is **aws_logo.png**.

Max_Concurrent_Download (positive)

Control the maximum number of parallel downloads accepted by the download manager. The default value is **25**.

Max_Connection (positive)

This is the maximum number of simultaneous connections for the server. This can be used when calling the *AWS.Server.Start*. The default is **5**.

Note that the total number of threads used by a server is:

```
N = <main server thread> + <max connections> [+ <session>]
```

Note: [...] means optional value Add 1 only if the session feature is activated. This is due to the session cleaner task.

Max_POST_Parameters (positive)

The maximum number of POST parameters supported by AWS. The default value is **100**.

Max_WebSocket (positive)

The maximum number of WebSocket that can be opened simultaneously in AWS. Above this value AWS will try to close timed-out WebSockets (see *WebSocket_Timeout*). The default value is **512**.

Max_WebSocket_Handler (positive)

The maximum number of message to handle simultaenously. The default value is **2**.

MIME_Types (string)

The name of the file containing the MIME types associations. The default file name is **aws.mime**.

Receive_Timeout (duration)

Number of seconds to timeout when receiving chunk of data. The default is **30.0** seconds.

Reuse_Address (boolean)

Set the socket reuse address policy. If set to True the server will be able to bind to a socket that has just been released without the need of waiting. Enabling this feature may introduce security risks on some platforms. The default is **FALSE**.

Security_Mode (string)

Set the security mode to use for the secure connections. The default mode is **TLS**. See *AWS.Net.SSL*.

Send_Buffer_Size (positive)

This is the socket internal buffer used for sending data to the clients. The default is **0**.

Send_Timeout (duration)

Number of seconds to timeout when sending chunk of data. The default is **40.0** seconds.

Server_Header (string)

The value to be used for the HTTP Server header. The default is **AWS (Ada Web Server) v20.0w**. If the value is set to the empty string, the server header is not sent.

Server_Host (string)

> The name of the host machine. This can be used if a computer has more than one IP address, it is possible to have two servers at the same port on the same machine, both being binded on different IP addresses.

Server_Name (string)

> The name of the server. This can be used when calling *AWS.Server.Start*. The default is **AWS Module**.

Server_Priority (natural)

> Priority of the task handling the HTTP protocol. The default is Default_Priority.

Server_Port (integer)

> The port where server will wait for incoming connections requests. This can be used when calling *AWS.Server.Start*. The default is **8080**.

Service_Priority (natural)

> Priority of the tasks used by optional services like SMTP Server, Server Push, Jabber and the Transient Page cleaner. The default is **Default_Priority**.

Session (boolean)

> Whether the session support must be activated or not. The default is **FALSE**.

Session_Name (string)

> The name of the cookie session. This can be used to support sessions for multiple servers embedded into the same executable. The default is **AWS**.

Session_Id_Length (positive)

> The length of the session id in characters. The default is **11** characters.

Session_Lifetime (duration)

> Number of seconds to keep session information. After this period a session is obsoleted and will be removed at next cleanup. The default is **600.0** seconds.

Session_Cleanup_Interval (duration)

> Number of seconds between each run of the session cleanup task. This task will remove all session data that have been obsoleted. The default is **300.0** seconds.

Session_Cleaner_Priority (natural)

> Priority of the task cleaning the session data. The default is **Default_Priority**.

Status_Page (string)

> The name of the status page to used. The default is **aws_status.thtml**.

TCP_No_Delay (boolean)

> This control the server's socket delay/no-delay option. This option should be used for applications that require lower latency on every packet sent. The default is **FALSE**.

TLS_Ticket_Support (boolean)

> Specify whether the TLS ticket support is activated or not. The default value is **FALSE**.

Transient_Cleanup_Interval (positive)

> Specify the number of seconds between each run of the cleaner task to remove transient pages. The default value is **180.0** seconds.

Transient_Lifetime (duration)

Specify the number of seconds to keep a transient page. After this period the transient page is obsoleted and will be removed during next cleanup. The default value is **300.0** seconds.

Trusted_CA (string)

This must point to the file containing the list of trusted Certificate Authorities. The CA in this file will be used to verify the client certificate validity. The default values is **<not-defined>**.

Up_Image (string)

The name of the up arrow image to use in the status page. The default is **aws_up.png**.

Upload_Directory (string)

This is to set the directory where upload files must be stored. By default uploaded files are written in the current directory. The default is **<not-defined>**.

User_Agent (string)

The value to be used for the HTTP User_Agent header. The default value is **AWS (Ada Web Server) v20.0w**. If the value is set to the empty string, the User_Agent header is not sent.

WebSocket_Message_Queue_Size (positive)

This is the size of the queue containing incoming messages waiting to be handled by one of the task, see Max_WebSocket_Handler above. The default value is **10**.

WebSocket_Origin (string)

This is a regular expression which can be used to handle WebSockets originating from a specific domain. By default AWS handles WebSockets from any origins.

WebSocket_Priority (natural)

Priority of the task handling the WebSockets. The default is **Default_Priority**.

WebSocket_Timeout (duration)

A number of seconds after which a WebSocket without activity is considered timed-out and can be elected to be closed if the maximum number of sockets opened has been reached. (see *Max_WebSocket*). The default is **28800.0**.

WWW_Root (string)

This option sets the Web Server root directory. All Web resources are referenced from this root directory. The default value is **./**.

Each option value can be retrieved using the *AWS.Config* unit or set using *AWS.Config.Set*.

For example to build a server where the *port* and the maximum number of *connection* can be changed via a configuration file (either `aws.ini` or `<program_name>.ini`):

```
WS   : AWS.Server.HTTP;

Conf : constant AWS.Config.Object := AWS.Config.Get_Current;

Server.Start (WS, Service'Access, Conf);
```

3.5 Session handling

AWS provides a way to keep session data while users are browsing. It works by creating transparently a session ID where it is possible to insert, delete and retrieve session data using a standard Ada API (see *AWS.Session*.). Session

data are key/value pair each of them being strings. These sessions data are kept on the server, for client side state management see *HTTP state management*.

- First you declare and start an HTTP channel with session enabled:

```
WS : AWS.Server.HTTP;

Server.Start (WS,
              Port    => 1234,
              Callback => Service'Access,
              Session  => True);
```

Here we have built an HTTP channel with a maximum of 3 simultaneous connections using the port 1234. A session ID will be created and sent inside a cookie to the client's browser at the first request. This session ID will be sent back to the server each time the client will ask for a resource to the server.

- Next, in the Service callback procedure that you have provided you must retrieve the Session ID. As we have seen, the callback procedure has the following prototype:

```
function Service (Request : in AWS.Status.Data) return AWS.Response.Data;
```

The Session ID is kept in the Request object and can be retrieved using:

```
Session_ID  : constant AWS.Session.ID := AWS.Status.Session (Request);
```

- From there it is quite easy to get or set some session data using the provided API. For example:

```
declare
   C : Integer;
begin
   C := AWS.Session.Get (Session_ID, "counter");
   C := C + 1;
   AWS.Session.Set (Session_ID, "counter", C);
end;
```

This example first get the value (as an Integer) for session data whose key is "*counter*", increment this counter and then set it back to the new value.

It is also possible to save and restore all session data. It means that the server can be shutdown and launched some time after and all client data are restored as they were at shutdown time. Client will just see nothing. With this feature it is possible to shutdown a server to update its look or because a bug has been fixed for example. It is then possible to restart it keeping the complete Web server context.

3.6 HTTP state management

AWS provides a full implementation of RFC 2109 via the *AWS.Cookie* package. Using this package you set, get and expire client-side HTTP cookies.

First we set a cookie:

```
declare
   Content : AWS.Response.Data;
begin
   AWS.Cookie.Set (Content,
                   Key      => "hello",
                   Value    => "world",
```

```
                    Max_Age  => 86400.0);
end;
```

Here we set the cookie *hello* with the value *world*, and we tell the client to expire the cookie 86400 seconds into the future.

Getting the cookie value back is equally simple:

```
declare
   Request : AWS.Status.Data
   --  Assume that this object contain an actual HTTP request.
begin
   Put_Line (AWS.Cookie.Get (Request, "hello"));
   --  Output 'world'
end;
```

Had the cookie *hello* not existed, an empty *String* would've been returned.

In some cases it might be of value to know if a given cookie exists, and for that we have the *Exists* function available:

```
declare
   Request : AWS.Status.Data
   --  Assume that this object contain an actual HTTP request
begin
   if AWS.Cookie.Exists ("hello") then
      Put_Line ("The 'hello' cookie exists!");
   end if;
end;
```

Note that *Exists* doesn't care if the cookie contains an actual value or not. If a cookie with no value exists, *Exists* will return *True*.

And finally we might wish to tell the client to expire a cookie:

```
declare
   Content : AWS.Response.Data;
begin
   AWS.Cookie.Expire (Content,
                      Key  => "hello");
end;
```

The Cookie package provide *Get* functions and *Set* procedures for *String*, *Integer*, *Float* and *Boolean* types, but since cookies are inherently strings, it's important to understand what happens when the cookie *String* value can't be converted properly to either *Integer*, *Float* or *Boolean*.

So if either conversion fails or the cookie simply doesn't exist, the following happens:

- For *Integer*, the value 0 is returned

- For *Float*, the value 0.0 is returned.

- For *Boolean*, the value *False* is returned. Note that only the string 'True' is *True*. Everything else is *False*.

For more information see *AWS.Cookie*.

3.7 Authentication

AWS supports **Basic** and **Digest** authentication. The authentication request can be sent at any time from the callback procedure. For this the *AWS.Response.Authenticate* message must be returned.

The authentication process is as follow:

- Send authentication request

  From the callback routine return an authentication request when needed:

```
function Service (Request : in Status.Data) return Response.Data is
   URI  : constant String := Status.URI (Request);
   User : constant String := Status.Authorization_Name (Request);
begin
   --  URI starting with "/prot/" are protected
   if URI (URI'First .. URI'First + 5) = "/prot/"
     and then User = ""
   then
      return Response.Authenticate ("AWS", Response.Basic);
```

  The first parameter is the **Realm**, it is just a string that will be displayed (on the authentication dialog box) by the browser to indicate for which resource the authentication is needed.

- Check authentication

  When an authentication as been done the callback's request data contain the user and password. Checks the values against an ACL for each protected resources:

```
function Protected_Service
  (Request : in AWS.Status.Data) return AWS.Response.Data
is
   User : constant String := Status.Authorization_Name (Request);
   Pwd  : constant String := Status.Authorization_Password (Request);
begin
   if User = "xyz" and then Pwd = "azerty" then
      return ...;
```

Note that the **Basic** authentication is not secure at all. The password is sent unencoded by the browser to the server. If security is an issue it is better to use the **Digest** authentication and/or an **SSL** server.

3.8 File upload

File upload is the way to send a file from the client to the server. To enable file upload on the client side the Web page must contain a **FORM** with an **INPUT** tag of type **FILE**. The **FORM** must also contain the **enctype** attribute set to *multipart/form-data*:

```
<FORM enctype="multipart/form-data" ACTION=/whatever METHOD=POST>
  File to process: <INPUT NAME=filename TYPE=FILE>
  <INPUT TYPE=SUBMIT NAME=go VALUE="Send File">
</FORM>
```

On the server side, *AWS* will retrieve the file and put it into the upload directory. *AWS* add a prefix to the file to ensure that the filename will be unique on the server side. The upload directory can be changed using the configuration options. See *Configuration options*.

The uploaded files are removed after the user's callback. This is done for security reasons, if files were not removed it would be possible to fill the server hard disk by uploading large files to the server. This means that uploaded files must be specifically handled by the users by either copying or renaming them.

AWS will also setup the form parameters as usual. In the above example there is two parameters (see *Form parameters*).

filename

> This variable contains two values, one with the client side name and one with the server side name.

First value : Parameters.Get (P, "filename")

> The value is the full pathname of the file on the server. (i.e. the upload directory catenated with the prefix and filename).

Second value : Parameters.Get (P, "filename", 2)

> The value is the simple filename (no path information) of the file on the client side.

go

> The value is "Send File"

3.9 Communication

This API is used to do communication between programs using the HTTP GET protocol. It is a very simple API not to be compared with *GLADE* or *SOAP*. This communication facility is to be used for simple request or when a light communication support is needed. For more complex communications or to achieve inter-operability with other modules it is certainly a good idea to have a look at the *AWS/SOAP* support, see *SOAP*.

In a communication there is a Client and a Server. Here is what is to be done on both sides to have programs talking together.

3.9.1 Communication - client side

On the client side it is quite simple. You just have to send a message using *AWS.Communication.Client.Send_Message*:

```
function Send_Message
  (Server     : in String;
   Port       : in Positive;
   Name       : in String;
   Parameters : in Parameter_Set := Null_Parameter_Set)
   return Response.Data;
```

The message is sent to the specified server using the given port. A message is composed of a name which is a string and a set of parameters. There is a parameter set constructor in *AWS.Communication*. This function return a response as for any callback procedure.

3.9.2 Communication - server side

On the server side things are a bit more complex but not that difficult. You must instantiate the *AWS.Communication.Server* generic package by providing a callback procedure. This callback procedure will must handle all kind of message that a client will send.

During instantiation you must also pass a context for the communication server. This context will be passed back to the callback procedure:

```
generic

   type T (<>) is limited private;
   type T_Access is access T;

   with function Callback
      (Server     : in String;
       Name       : in String;
       Context    : in T_Access;
       Parameters : in Parameter_Set := Null_Parameter_Set)
       return Response.Data;

package AWS.Communication.Server is
   ...
```

A complete example can be found in the demos directory. Look for `com_1.adb` and `com_2.adb`.

Note that this communication API is used by the Hotplug module facility, see *Hotplug module*.

3.10 Hotplug module

An **Hotplug module** is a module that can by dynamically binded to a running server. It is a Web server and the development process is very similar to what we have seen until now *Building an AWS server*. The Hotplug module will register itself into a Web server by sending a message using the communication API. The Hotplug module send to the server a regular expression and an URL. The main server will redirect all URL matching the regular expression to the Hotplug module.

Note that the main server will redirect the URL to the first matching regular expression.

3.10.1 Hotplug module - server activation

The first step is to properly create the main server hotplug module registration file. This file must list all hotplug modules that can register into the main server. Each line have the following format:

```
hotplug_module_name:password:server:port
```

hotplug_module_name

> The name of the hotplug module. You can choose any name you want. This name will be use during the registration process and to generate the password.

password

> The MD5 password, see below.

server

> The name of the server where the redirection will be made. This is for security reasons, main server will not permit to redirect requests to any other server.

port

> The port to use for the redirection on *server*.

You must create a password for each hotplug modules. The generated password depends on the hotplug module name. A tool named *aws_password* is provided with *AWS* to generate such password. Usage is simple:

```
$ aws_password <hotplug_module_name> <password>
```

Then, after starting the main server you must activate the Hotplug feature:

```
AWS.Server.Hotplug.Activate (WS'Unchecked_Access, 2222, "hotplug_conf.ini");
```

`hotplug_conf.ini` is the hotplug module registration file described above.

3.10.2 Hotplug module - creation

Here is how to create an Hotplug module:

- First you create a standard Web server, see *Building an AWS server*:

```
WS : AWS.Server.HTTP (3, 1235, False, Hotplug_CB.Hotplug'Access, False);
```

Here we have a server listening to the port 1235. This server can be used alone if needed as any Server developed with AWS.

- Then you register the Hotplug module to the main server, see *AWS.Client.Hotplug*:

```
Response := AWS.Client.Hotplug.Register
             (Name     => "Hotplug_Module_Demo",
              Password => "my_password",
              Server   => "http://dieppe:2222",
              Regexp   => ".*AWS.*",
              URL      => "http://omsk:1235/");
```

The hotplug module *Hotplug_Module_Demo* must have been declared on the main server, the password and redirection must have been properly recorded too for security reasons, see *Hotplug module - server activation*. This command register *Hotplug_Module_Demo* into the server running on the machine *dieppe* and ask it to redirect all *URL* containing *AWS* to the server running on machine *omsk* on port *1235*.

- When the Hotplug module is stopped, you must unregister it:

```
Response := AWS.Client.Hotplug.Unregister
             (Name     => "Hotplug_Module_Demo",
              Password => "my_password",
              Server   => "http://dieppe:2222",
              Regexp   => ".*AWS.*");
```

Here we ask to unregister *Hotplug_Module_Demo* from server *dieppe*. As for the registration process a proper password must be specified, see *Hotplug module - server activation*.

A complete example can be found in the demos directory. Look for `main.adb` and `hotplug.adb`.

3.11 Server Push

This protocol is obsolescent, it is hightly recommended to use the WebSockets now. See *WebSockets*.

Server Push is a feature that let the Web Server send continuously data to client's Web Browser or client applications. The client does not have to reload at periodic time (which is what is called client pull) to have the data updated, each time the server send a piece of data it gets displayed on the client.

To build a push server you need to build an instance of the *AWS.Server.Push* package. This package takes a set of formal parameters. Here are the step-by-step instructions to build a Push Server:

- The data to be sent

  First you must create a type that will contains the data to be sent to client's browser except if it is a standard Ada type. See *Client_Output_Type* formal parameter.

- The data that will be streamed

  This is the representation of the data that will be sent to client's browser. This will be either a *String* for Web pages or *Stream_Element_Array* for binary data like pictures. See *Stream_Output_Type* formal parameter.

- The context

  It is often nice to be able to configure each client with different parameters if needed. This can be achieved with the Context data type that will be passed as parameter of the conversion function described below. See *Client_Environment* formal parameter.

- Provides a function to convert from the data type to be sent to the data that will be streamed.

  This is a function that will transform the data described on point 1 above to the form described on point 2 above. See *To_Stream_Output* formal parameter.

- Build the Push Server

  To do so you just need to instantiate *AWS.Server.Push* with the above declarations.

- Registering new clients

  In the standard *AWS* procedure callback it is possible to register a client if requested. This is done by calling *AWS.Server.Push.Register*. It is possible to unregister a client using *AWS.Server.Push.Unregister*. Each client must be identified with a unique client ID. After registering a new client from the callback procedure you must return the *AWS.Response.Socket_Taken* message. This is very important, it tells the server to not close this socket.

- Sending the data

  At this point it is possible to send data to clients. To do so two routines are available.

AWS.Server.Push.Send_To

  To send a piece of data to a specific client identified by its client ID.

AWS.Server.Push.Send

  To send a piece of data to all clients registered on this server.

Very large Internet applications should use this feature carefully. A push server keeps a socket reserved for each registered clients and the number of available sockets per process is limited by the OS.

3.12 Working with Server sockets

With *AWS* is is possible to take out a socket from the server and give it back later. This feature must be used carefully but it gives a lot of flexibility. As the socket is taken away, the connection line (or slot) is released, *AWS* can then use it to handle other requests.

This can be used to better support heavy loaded servers when some requests need a long time to complete. Long time here means longer than most of the other requests which should be mostly interractives for a Web server. Of course in such a case a keep-alive connection is kept open.

The usage in such a case is to take out the socket and put it in a waiting line. This releases the connection for the server. When the data to prepare the answer is ready you give back the socket to the server.

- Take a socket from the server

  This first step is done form the callback function. A user instead of replying immediatly decides to take away the socket from the server. The first step is to record the connection socket socket by calling *AWS.Status.Socket*. The second step is to tell the server to not release this socket by returning *AWS.Response.Socket_Taken* from the callback function. At this point the server will continue to serve other clients.

  Note that this feature is used by the server push implementation, see *Server Push*.

- Give back the socket to the server

  Calling *AWS.Sever.Give_Back_Socket* will register the socket for reuse. This socket will be placed into a spool, next time the server will check for incoming requests it will be picked up.

3.13 Server Log

It is possible to have the server activity logged into the file `<progname>-Y-M-D.log`. To activate the logging you must call the *AWS.Server.Log.Start*, and it is possible to stop logging by calling *AWS.Server.Log.Stop*. Note that *AWS.Server.Log.Start* have a parameter named *Auto_Flush* to control output buffering. This parameter is False by default. If set to True, the log file will be automatically flushed after each data. If the server logging is not buffered, i.e. Auto_Flush is False, the log can still be flushed by calling the *AWS.Server.Log.Flush* routine. See *AWS.Log* for more information especially about the way rotating logs can be setup. Using this feature it is possible to have automatic split of the log file each day, each month or at every run. See *AWS.Log* spec. This is very useful to avoid having very big log files.

The log format depend on Log_Extended_Fields configuration parameter. If this parameter is empty, the HTTP log would have fixed apache compartible format:

```
<client IP> - <auth name> - [<date and time>] "<request>" <status code> <size>
```

For example:

```
100.99.12.1 -  - [22/Nov/2000:11:44:14] "GET /whatever HTTP/1.1" 200 1789
```

If the extended fields list is not empty, the log file format would have user defined fields set:

```
#Version: 1.0
#Date: 2006-01-09 00:00:01
#Fields: date time c-ip cs-method cs-uri cs-version sc-status sc-bytes
2006-01-09 00:34:23 100.99.12.1 GET /foo/bar.html HTTP/1.1 200 30
```

Fields in the comma separated Log_Extended_Fields list could be:

date Date at which transaction completed

time Time at which transaction completed

time-taken Time taken for transaction to complete in seconds

c-ip Client side connected IP address

c-port Client side connected port

s-ip Server side connected IP address

s-port Server side connected port

cs-method HTTP request method

cs-username Client authentication username

cs-version Client supported HTTP version

cs-uri Request URI

cs-uri-stem Stem portion alone of URI (omitting query)

cs-uri-query Query portion alone of URI

sc-status Responce status code

sc-bytes Length of response message body

cs(<header>) Any header field name sent from client to server

sc(<header>) Any header field name sent from server to client

x-<appfield> Any application defined field name

AWS also support error log files. If activated every internal error detected by *AWS* will gets logged into this special file. Log file for errors would be in simple apache compartible format. See *AWS.Server.Log.Start_Error* and *AWS.Server.Log.Stop_Error*.

For the full set of routines supporting the log facility see *AWS.Server.Log* .

3.14 Secure server

It is not much difficult to use a secure server (*HTTPS*) than a standard one. Here we describe only what is specific to an HTTPS server.

Before going further you must check that *AWS* has been configured with *SSL* support. See *Building*. You must also have installed the *OpenSSL* or *GNUTLS* libraries on your system. If this is done, you can continue reading this section.

3.14.1 Initialization

A server is configured as using the HTTPS protocol at the time it is started. The only thing to do is to set the Start's Security parameter to True. This will start a server and activate the *SSL* layer by default. A secure server must use a valid certificate, the default one is **cert.pem**. This certificate has been created by the *OpenSSL* or *GNUTLS* tool and is valid until year 2008. Yet, this certificate has not been signed. To build a secure server user's can rely on, you must have a valid certificate signed by one of the **Certificate Authorities**.

The certificate to be used must be specified before starting the secure server with *AWS.Server.Set_Security*:

With a key and certificate files:

```
AWS.Server.Set_Security
  (WS,
   Key_Filename         => "server.key",
   Certificate_Filename => "server.crt");
```

Or with a self-contained certificate:

```
AWS.Server.Set_Security (WS, Certificate_Filename => "aws.pem");
```

Or using the *certificate* configuration parameter, see *Configuration options*.

3.14.2 Verify callback

First note that it is not necessary to use such callback to verify the certificate validity, see *Using a Certificate Authority*.

This callback will receive the client certificate as sent during SSL handshake between the server and the client. The certificate information can be checked for logging purpose or to impose some restriction. Generally this callback should return the value from *AWS.Net.SSL.Certificate.Verified*, see *AWS.Net.SSL.Certificate*.

The Verified status of the certificate is the one that has been issued by the SSL implementation during certificate verification and can generally be trusted.

3.14.3 Self-signed certificate

Creating a server certificate

The goal here is not to replace the *OpenSSL* documentation but just to present one way to create a self signed certificate for an *HTTPS* test server. Note that *GNUTLS* offers similar tools to generate certificates.

Generate a RSA key:

```
$ openssl genrsa -rand <filename> -out aws-server.key
```

Filename must point to any file, this is used to initialized the random seed.

Generate the certificate:

```
$ openssl req -new -x509 -days 730 -key aws-server.key -out aws-server.cert
```

Create a single self contained file (optional):

```
$ cat aws-server.key aws-server.cert > aws.pem
```

A this point you can use `aws.pem` with your server or the separate `server.key` and `server.crt` files.

It is also possible to sign the server's key. In this case the key won't be in plain text but will require to setup a password on the server code for the key to be decoded. See routine Set_Password_Callback in AWS.Net.SSL.Certificate.

Generate a crypted RSA key:

```
$ openssl genrsa -aes128 -passout pass:<PASSWORD> -out aws-server.key
```

Creating a client certificate

A certificate can also be used on a Web browser and passed to the server to have a strong client authentication. A client certificate must be *PKCS12*. The steps to generate such certificate are:

Generate a RSA key:

```
$ openssl genrsa -des3 -out aws-client.key
```

Filename must point to any file, this is used to initialized the random seed.

Generate the certificate:

```
$ openssl req -new -x509 -days 730 -key aws-client.key -out aws-client.cert
```

Create the corresponding PKCS12 certificate:

```
$ openssl pkcs12 -export -clcerts -in aws-client.cert -inkey aws-client.key -out␣
↪client.p12
```

3.14.4 Using a Certificate Authority

In this section we will use a Certificate Authority to signed the server certificates and the client certificates. Using this method is required if the server must ensure that only clients with a valid certificate will be able to connect to the server. The server will verify that the client certificate received has been signed by a known Certificate Authority.

Note that these checks are happening during the SSL handshake, so before the user's callback.

For this to work the following configuration options must be used:

Exchange_Certificate To request that the client certificate be sent.

Trusted_CA The file containing the certificate of the Certificate Authority we trust. The CA which has signed the client's certificate.

Certificate_Required If no certificate has been received from the client the server will reject the connection. If this is not set, we can still validate the client's certificate in the verify callback, see *Verify callback* and for example log the connecting users.

Initializing the Certificate Authority

First the Certificate Authority must be initialized on the computer. This is heavily dependent on the actual Operating System used, describing this part is out of scope of this document.

On GNU/Debian the default setup (see default_ca in `/etc/ssl/openssl.cnf`) can be used to create a **demo** Certificate Authority locally to test this feature:

```
$ mkdir demoCA
$ mkdir demoCA/newcerts
$ touch demoCA/index.txt
$ echo ABCC > demoCA/serial
$ echo 01 > demoCA/crlnumber
```

Creating the Certificate Authority

Generate a RSA key:

```
$ openssl genrsa -out private-ca.key 1024
```

Generate the certificate signing request:

```
$ openssl req -new -key private-ca.key -out private-ca.csr
```

During this step you'll be asked for information about the CA (Country, State or Province, Organization Name...).

Create the CA certificate:

```
$ openssl x509 -req -days 365 -in private-ca.csr -signkey private-ca.key -out private-
↪ca.crt
```

This certificate will be used by AWS as the trusted CA, see *Configuration options*.

Creating a CA signed server certificate

Generate a RSA key:

```
$ openssl genrsa -out aws-server.key 1024
```

Generate the certificate signing request:

```
$ openssl req -new -key aws-server.key -out aws-server.csr
```

During this step you'll be asked for information about the server (Country, State or Province, Common Name...). Note that the Organization Name here must match the one from the CA and the Common Name should be the server fully qualified domain name.

Create the server certificate, signed it with our CA:

```
$ openssl ca -in aws-server.csr -cert private-ca.crt -keyfile private-ca.key -out aws-
→server.crt
```

Create a single self contained file (optional):

```
$ cat aws-server.key aws-server.cert > aws.pem
```

Creating a CA signed client certificate

Generate a RSA key:

```
$ openssl genrsa -des3 -out aws-client.key 1024
```

Generate the certificate signing request:

```
$ openssl req -new -key aws-client.key -out aws-client.csr
```

During this step you'll be asked for information about the client (Country, State or Province, Common Name...). Note that the Organization Name here must match the one from the CA and the Common Name should be the client's one.

Create the client certificate, signed it with our CA:

```
$ openssl ca -in aws-client.csr -cert private-ca.crt -keyfile private-ca.key -out aws-
→client.crt
```

Create the corresponding PKCS12 certificate:

```
$ openssl pkcs12 -export -clcerts -in aws-client.crt -inkey aws-client.key -out aws-
→client.p12
```

Creating a Certificate Revocation List (CRL)

A Certificate Revocation List is used to revoke some client's certificates. Those clients won't be able to connect to the secure server anymore. Using the CA created above the following commands can be used to create a CRL.

Revoke the certificate:

```
$ openssl ca -cert private-ca.crt -keyfile private-ca.key -revoke aws-client.crt
```

Generate the CRL:

```
$ openssl ca -cert private-ca.crt -keyfile private-ca.key -gencrl -out crl.pem -
→crldays 30
```

The file `crl.pem` is the one to install on the server using the CRL_File configuration option, see *Configuration options*. This file contains the list of all revoked certificates for the corresponding CA.

3.14.5 Security level

This table summarize the security level achieved with different settings of the security oriented configuration parameters.

Security	SSL	Exchange Certificate	Certificate required	Trusted CA
Data between the client and the server are encrypted.	Yes	No	No	No
Client can be identified, it is still possible to access the server without having a certificate.	Yes	Yes	No	No
Client are identified, a certificate is required. The verification of the validity is up to the application using the verify callback.	Yes	Yes	Yes	No
Client are identified and verified, the certificate must have been signed by a Certificate Authority. It is not possible to access the server without a valid certificate.	Yes	Yes	Yes	Yes

3.14.6 Protocol

There are different security options, either *SSLv2*, *SSLv3* or *TLSv1*. *SSLv2* and *SSLv3* are supported by most if not all Web browsers. These are the default protocol used by *AWS*.

TLSv1 is not supported at this point.

3.15 Unexpected exception handler

When *AWS* detects an internal problem, it calls a specific handler. This handler can be used to log the error, send an alert message or build the answer to be sent back to the client's browser.

Here is the spec for this handler:

```
type Unexpected_Exception_Handler is access
  procedure (E      : in     Ada.Exceptions.Exception_Occurrence;
             Log    : in out AWS.Log.Object;
             Error  : in     Data;
             Answer : in out Response.Data);
```

The handler can be called in two modes:

Non fatal error (Error.Fatal is False)

> In this case *AWS* will continue working without problem. A bug has been detected but it was not fatal to the thread (slot in *AWS*'s terminology) handling. In this case it is possible to send back an application level message to the client's browser. For that you just have to fill the unexpected handler's *Answer* parameter with the right response message. The *Error* parameter receive information about the problem, see *AWS.Exceptions*.

Fatal error (Error.Fatal is True)

> In this case *AWS* will continue working but a thread (slot number *Error.Slot* in *AWS*'s terminology) will be killed. It means that *AWS* will have lost one the simultaneous connection handler. The server will continue working unless it was the last slot handler available. Note that a Fatal error means an *AWS* internal bug and it should be reported if possible. In this mode there is no way to send back an answer to the client's browser and *Error* value must be ignored.

The default handler for unexpected exceptions send a message to standard error for fatal errors. For non fatal errors it log a message (if the error log is activated for the server) and send back a message back to the client. The message is either a built-in one or, if present in the server's directory, the content of the `500.tmplt` file. This templates can used the following tags:

AUTH_MODE

> The authorization mode (Either NONE, BASIC or DIGEST).

EXCEPTION

> Exception information with traceback if activated.

HTTP_VERSION

> Either HTTP/1.0 or HTTP/1.1

METHOD

> The request method (Either GET, HEAD, POST or PUT)

PAYLOAD

> The full *XML* payload for *SOAP* request.

PEERNAME

> The IP address of the client

SOAP_ACTION

> Either True or False. Set to True for a *SOAP* request.

URI

> The complete URI

For more information see *AWS.Server* and *AWS.Exceptions*.

3.16 Socket log

To ease *AWS* applications debugging it is possible to log all data sent/received to/from the sockets. For this you need to call the *AWS.Net.Log.Start* routine by passing a write procedure callback. You have to create such procedure or use one read-to-use provided in *AWS.Net.Log.Callbacks* package.

For more information see *AWS.Net.Log* and *AWS.Net.Log.Callbacks*.

3.17 Client side

AWS is not only a server it also implement the HTTP and HTTPS protocol from the client side. For example with *AWS* it is possible to get a Web page content using the *AWS.Client* API, see *AWS.Client*.

It also support client **Keep-Alive** connections. It is then possible to request many URI from the same server using the same connection (i.e. the same sockets).

AWS client API also support proxy, proxy authentication and Web server authentication. Only basic (and not digest) authentication is supported at this time.

Let's say that you want to retrieve the *contrib.html* Web page from Pascal Obry's homepage which is http://perso. wanadoo.fr/pascal.obry. The code to do so is:

```
Data := Client.Get
         (URL => "http://perso.wanadoo.fr/pascal.obry/contrib.html");
```

From there you can ask for the result's content type:

```
if Response.Content_Type (Data) = "text/html" then
   ...
end if;
```

Or using the MIME types defined in *AWS.MIME* unit:

```
if Response.Content_Type (Data) = MIME.Text_HTML then
   ...
end if;
```

And display the content if it is some kind of text data:

```
Text_IO.Put_Line (Response.Message_Body (Data));
```

If the content is some kind of binary data (executable, PNG image, Zip archive...), then it is possible to write the result to a file for example. Look at the *agent* program in the *demos* directory.

If the Web page is protected and you must pass the request through an authenticating proxy, the call will becomes:

```
Data := Client.Get
         (URL         => "http://www.mydomain.net/protected/index.html"
          User        => "me",
          Pwd         => "mypwd",
          Proxy       => "192.168.67.1",
          Proxy_User  => "puser",
          Proxy_Pwd   => "ppwd");
```

The client upload protocol is implemented. Using *AWS.Client.Upload* it is possible to send a file to a server which support the file upload protocol.

HIGH LEVEL SERVICES

Here you will find a description of high level services. These services are ready to use with AWS and can be used together with user's callbacks.

Refer to the Ada spec for a complete API and usage description.

4.1 Directory browser

This service will help building a Web directory browser. It has a lot of options to sort directory entries and is based on the templates interface *AWS.Templates*. This means that you can use the default directory template or provide your own.

see *AWS.Services.Directory* for complete spec and services descriptions.

4.2 Dispatchers

In many AWS applications it is needed to check the URI to give the right answer. This means that part of the application is a big **if/elsif** procedure. Also, in standard callback it is not possible to have user data. Both of these restrictions are addressed with the Dispatchers facilities.

Working with a dispatcher is quite easy:

- Create a new dispatcher by inheriting from the service you want to build.

- Register a set of action based on rules (strings, regular expressions depending on the service)

4.2.1 Callback dispatcher

This is a wrapper around the standard callback procedure. It is needed to mix dispatcher based callback and access to procedure callback. Note that it is not in the *AWS.Services.Dispatchers* hierarchy but in *AWS.Dispatchers.Callback* because this is a basic service needed for the server itself. It is referenced here for documentation purpose but an AWS server can be built with using it.

see *AWS.Dispatchers.Callback* for complete spec description.

4.2.2 Method dispatcher

This is a dispatcher based on the request method. A different callback procedure can be registered for the supported request methods: GET, POST, PUT, HEAD.

see *AWS.Services.Dispatchers.Method* for complete spec description.

4.2.3 URI dispatcher

This is a dispatcher based on the request resource. A different callback procedure can be registered for specific resources. The resource is described either by its full name (string) or a regular expression.

see *AWS.Services.Dispatchers.URI* for complete spec description.

4.2.4 Virtual host dispatcher

This is a dispatcher based on the host name. A different callback procedure can be registered for specific host. This is also known as virtual hosting.

The same computer can be registered into the DNS with different names. So all names point to the same machine. But in fact you want each name to be seen as a different Web server. This is called virtual hosting. This service will just do that, call different **callback** procedures or redirect to some **machine/port** based on the host name in the client's request.

see *AWS.Services.Dispatchers.Virtual_Host* for complete spec description.

4.2.5 Transient pages dispatcher

This is a dispatcher that calls a user's callback and if the resource requested is not found (i.e. the user's callback returns status code 404) it checks if this resource is known as a transient page. see *Transient Pages*.

4.2.6 Timer dispatcher

A timer dispatcher can be used to call different callback routines depending on the current date and time. Such dispatcher is composed of a set of *Period* activated. When the current date and time is inside a *Period* the corresponding callback is called. A *Period* can eventually be repeated. Here are the different kind of *Period* supported by *AWS*:

Once A unique period in time. The boundaries are fully described using a year, month, day, hour, minute and second.

Yearly A period that repeats each year. The boundaries are described using a month, day, hour, minute and second.

Monthly A period that repeats each month. The boundaries are described using a day, hour, minute and second.

Weekly A period that repeats each week. The boundaries are described using a day name, hour, minute and second.

Daily A period that repeats each day. The boundaries are described using an hour, minute and second.

Hourly A period that repeats each hour. The boundaries are described using a minute and second.

Minutely A period that repeats each minute. The boundaries are described using a second.

4.2.7 Linker dispatcher

A dispatcher that can be used to chain two dispatchers. The response of the first dispatcher is returned except if it is a 404 (Not Found) error. In this case, the response of the second dispatcher is returned.

4.2.8 SOAP dispatcher

AWS provides also a *SOAP* specific dispatcher. This is a way to automatically route HTTP requests or *SOAP* requests to different callback routines.

see *SOAP helpers* for more information. see *SOAP.Dispatchers.Callback* for complete spec description.

4.3 Static Page server

This service is a ready to use static page server callback. Using it is possible to build a simple static page server, as simple as:

```ada
with AWS.Server;
with AWS.Services.Page_Server;

procedure WPS is
   WS : AWS.Server.HTTP;
begin
   AWS.Server.Start
     (WS, "Simple Page Server demo",
      Port           => 8080,
      Callback       => AWS.Services.Page_Server.Callback'Access,
      Max_Connection => 5);

   AWS.Server.Wait (AWS.Server.Q_Key_Pressed);

   AWS.Server.Shutdown (WS);
end WPS;
```

Build this program and launch it, it will server *HTML* pages and images in the current directory.

It is possible to activate the directory browsing facility of this simple page server. This is not activated by default. This feature is based on the directory browsing service see *Directory browser*.

Note that this service uses two template files:

aws_directory.thtml The template page used for directory browsing. See see *AWS.Services.Directory* for a full description of this template usage.

404.thtml The Web page returned if the requested page is not found. This is a template with a single tag variable named PAGE. It will be replaced by the ressource which was not found.

Note that on Microsoft IE this page will be displayed only if the total page size is bigger than 512 bytes or it includes at least one image.

see *AWS.Services.Page_Server* for a complete spec description.

4.4 Transient Pages

A transient page is a resource that has a certain life time on the server. After this time the resource will be released and will not be accessible anymore.

Sometimes you want to reference, in a Web page, a resource that is built in memory by the server. This resource can be requested by the client (by clicking on the corresponding link) or not, in both cases the page must be released after a certain amount of time to free the associated memory.

This is exactly what the transient pages high level service do automatically. Each transient page must be registered into the service, a specific routine named *Get_URI* can be used to create a unique *URI* on this server. see *AWS.Services.Transient_Pages*.

A transient pages dispatcher can be used to build a transient pages aware server. see *Transient pages dispatcher*.

4.5 Split pages

It not not very convenient to send back a Web page with a large table. In such a case it is better to split the table in chunks (20 lines or so) and to send only the first page. This page reference the next pages and can also contains an index of the pages.

The *AWS*'s split page feature can automatically do that for you. Given template *Translate_Table* or *Translate_Set* and the max line per page it returns the first page and create a set of transient pages for all other pages. A set of template tags are used to reference the previous and next page and also to build the page index.

There is different ways to split a set of pages and ready-to-use splitters are available:

Alpha Split in (at most) 28 pages, one for empty fields, one for all fields that start with a digit, and one for each different initial letter. see *AWS.Services.Split_Pages.Alpha*.

Alpha.Bounded Same as the alpha splitter, but pages larger than a Max_Per_Page value are further splitted. A secondary index is generated that gives the various pages for a given letter. see *AWS.Services.Split_Pages.Alpha.Bounded*.

Uniform Split in pages of length Max_Per_Page (except the last one). This corresponds to the default service in Split_Pages package. see *AWS.Services.Split_Pages.Uniform*.

Uniform.Alpha Same as the uniform splitter, but builds in addition an alphabetical secondary index from a key field. see *AWS.Services.Split_Pages.Uniform.Alpha*.

Uniform.Overlapping Same as the uniform splitter, but pages (except the first one) repeat Overlap lines from the previous page in addition to the Max_Per_Page lines. see *AWS.Services.Split_Pages.Uniform.Overlapping*.

Using the spliter abstract interface it is possible to build a customized splitter algorithm. see *AWS.Services.Split_Pages*.

4.6 Download Manager

A server that need to handle lot of large downloads can run out of connection to answer the standard Web pages. A solution is to increase the number of simultaneous connections, but this is not really efficient as a task is created for each connection and does not ensure that all the connections will be used for the downloads anyway.

The download manager can be used for that, and provides the following feature:

- use a single task for all downloads
- can be configured to limit the number of simultaneous connections
- downloads past this limit are queued
- send messages to the client with the position in the waiting line
- send messages to the client when the download is about to start

The server must be configured to use dispatchers (standard callbacks are not supported, note that it is possible to create a dispatcher for standard callbacks. see *AWS.Dispatchers.Callback*).

To start the download manager you need to pass the main server dispatcher object. The start routine will return a new dispatcher, linked with the download server specific dispatcher, that must be used to start the standard Web server. See comment in see *AWS.Services.Download*.

To queue a download request in the download manager you just need to create a stream object (can be any kind of stream, see *AWS.Resources.Streams.**) for the resource to download.

The download manager needs two templates files:

aws_download_manager_waiting.thtml This template is used for sending a message to the client when the request is on the waiting line. The tags defined in this template file are:

> *NAME* the name of the resource to download (the filename), this is the default filename used for the client side save dialog.

> *RES_URI* the URI used to access the resource.

> *POSITION* the position in the waiting line (not counting the current served clients).

aws_download_manager_start.thtml This template is used for sending a message to the client when the download is about to start (the request is out of the waiting line). The tags defined in this template file are:

> *NAME* as above

> *RES_URI* as above

It is important to note that those templates must be reloaded periodically. The best way to do that in the context of an *HTML* document is to use a meta-tag. For example to refresh the page every two seconds:

```
<meta http-equiv="refresh" content="2">
```

The templates could look like:

aws_download_manager_waiting.thtml

```
<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.01//EN"
 "http://www.w3.org/TR/html4/strict.dtd">
  <html>
    <head>
      <meta http-equiv="refresh" content="2">
      <title>Download Manager - waiting</title>
    </head>
    <body>
      <p>Waiting for downloading @_NAME_@
      <p>Position in the waiting line @_POSITION_@
    </body>
  </html>
```

aws_download_manager_start.thtml

```
<!DOCTYPE HTML PUBLIC "-//W3C//DTD HTML 4.01//EN"
 "http://www.w3.org/TR/html4/strict.dtd">
  <html>
    <head>
      <meta http-equiv="refresh" content="2">
      <title>Download Manager - waiting</title>
    </head>
    <body>
      <p>Waiting for downloading @_NAME_@
      <p>The download will start in a moment
    </body>
  </html>
```

4.7 Web Elements

AWS provides some components to help creating nice looking Web interfaces. It is possible to browse those Web Elements using the *web_elements* demo. Just launch this Web application from the demos directory and turn your Web browser to http://localhost:2400.

Currently *AWS* provides:

- Notebooks (based on CSS)

- CSS Menu

- Rounded boxes

- Ajax

All of them are based on templates to be easily reused in other applications. The three first are best described by the Web Elements demos as they are 100% design. The *Ajax* one is a bit more complex, we will present its use in the following section.

4.7.1 Installation

To ease integration we have used the following design:

- Sub-directories found in the *AWS*'s web_elements directory are self contained. The content must be copied into the project. Note that the icons and javascripts directories contain the icons and javascripts code shared by all web elements and must also be copied, see below.

- Each graphic elements (icons) is referenced into the templates with the alias */we_icons/<icon_name>*. So users must provide the right alias ("*/we_icons/*") in the Web server.

- Each JavaScripts code is referenced into the templates with the alias */we_js/<script>*. So users must provide the right alias (*"/we_js/"*) in the Web server.

4.7.2 Ajax

First of all, *Ajax* stand for *Asynchronous JavaScript language and XML*, and is not well defined at the moment. *Ajax* is on one side able to send HTTP requests to the Web server and on the other side able to manipulate directly the Web browser's *DOM* tree. On the *DOM* it can add, remove or replace *XML* nodes. So, it is possible to change the content of a Web page without reloading it from the server.

Most importantly, *Ajax* changes the way Web applications are thought from **page** based to **event** based.

As implemented into *AWS*, *Ajax* support comes as a set of *JavaScript* templates. Using those templates there is no need to know *JavaScript* (except for the *JavaScript* event names) and it makes *Ajax* programming lot easier. Two actions are provided, one for replacing another for clearing part of the web page content.

Steps to do Ajax

What are the steps to do *Ajax* ?

Remember, do not think about the Web page but about a specific widget (*HTML* fragments) with the associated event and action.

- Include the AWS/Ajax support file

  This is the *AWS/Ajax* runtime, it contains *JavaScript* code needed for the *AWS/Ajax* support.

- Create the Web widgets/forms

  There is nothing special here, use your favorite Web designer tool.

- Create Web area

  Using some *HTML* <div> tags we create areas where we will place *HTML* fragments later. For example when clicking on a button (described above) in our Web interface we want to display a new form in this area.

- Name the widgets/forms/area using id=”name” attribute

  Give a different name to the widgets using id=”name”. This name will be later used to identify the widgets on which the envent and corresponding action must be placed. We do not want to clutter the Web design with *JavaScript* code like *onclick=”dothis()”* or *onchange=”dothat()”*.

- Add the proper event/action to the widgets using the AWS/Ajax templates

  This is the interresting part. At this point we link events/actions to the widgets and specify in which area the results sent by the server will be placed.

This is not the only way to do *Ajax*, we just presented here a simple approach that works well with the *AWS/Ajax* templates.

Basic Ajax support

This section describes the *AWS/Ajax* support where the answer from the server is an *HTML* fragment. This basic support is designed to be used for migration of a Web server to *Ajax*. For new applications, it is worth considering using the XML based Ajax support, see *XML based Ajax*.

Let's have a very simple example:

- The AWS/Ajax runtime support

  ```
  @@INCLUDE@@@ aws.tjs
  ```

  Must be included in every Web pages into the *<head>* tag.

- The widget: a button

  ```
  <input id="clickme" type="button" value="Clik Me">
  ```

- The result area: a div

  ```
  <div id="placeholder">... result here ...</div>
  ```

- The AWS/Ajax

  ```
  @@INCLUDE@@ aws_action_replace.tjs onclick clickme placeholder
  ```

  Basically it places an **onclick** attribute (the event) in the *HTML <input>* identified as **clickme** (the action) above. Here is what happen when the button is clicked:

  - send the "/onclick$clickme" HTTP request to the server

  - asynchronously wait for the answer, when received place the message body into the *<div>* **placeholder**.

On the server side the code would look like this:

```
function Callback (Request : in Status.Data) return Response.Data is
   URI : constant String := Status.URI (Request);
begin
   if URI = "/clickme" then
      return Response.Build (MIME.Text_HTML, "you click me!");
   ...
```

So when the button is clicked the string **"you click me!"** will replace the **"... result here ..."** string of the place holder div above.

This is a simple and very limited example as there is no parameter passed to the *HTTP* request. In real Web applications it is necessary to send a context with the request. This can be either the value of other widgets or all values of widgets' form.

References to widgets or forms can be passed to the `aws_action_replace.tjs` template starting with the 5th parameter:

```
<input id="field" type="text" value="default value">

...

@@INCLUDE@@ aws_action_replace.tjs (onclick clickme placeholder 5=>field)
```

or:

```
<form id="small_form" name="small_form">
...
</form>

@@INCLUDE@@ aws_action_replace.tjs (onclick clickme placeholder 5=>*mall_form)
```

Note that the *onclick* event is only one of the possible *JavaScript* event on a *button*. It is possible to used any supported event, for example on an *HTML <select>* widget it is common to map the action to the *onchange* event.

AWS also provides support for clearing an area or a widget content (like an input):

```
@@INCLUDE@@ aws_action_clear.tjs (onclick, clear, field)
```

This simple action adds the **onclick** event to the **clear** button to erase the content of the **field** widget.

XML based Ajax

In many cases you'll like to update and/or clear multiple areas in your Web interface. With the templates above only a single action is possible. *AWS* provides support for *XML* based answers. In this *XML* documents it is possible to:

- replace an area with a new content:

  ```
  <replace id="item_id">new text</replace>
  ```

- clear an area:

  ```
  <clear id="item_id"/>
  ```

- add an item into a select widget:

  ```
  <select action="add" id="item_id"
          option_value="value" option_content="content"/>
  ```

- remove an item from a select widget:

  ```
  <select action="delete" id="item_id" option_value="value"/>
  ```

- select a specific item in a select widget:

  ```
  <select action="select" id="item_id" option_value="value"/>
  ```

- clear a select widget (remove all items):

```
<select action="clear" id="item_id"/>
```

- select a radio button:

```
<radio action="select" id="item_id"/>
```

- check a checkbox:

```
<check action="select" id="item_id"/>
```

- clear a checkbox:

```
<check action="clear" id="item_id"/>
```

- call another URL:

```
<get url="http://thishost/action">
  <parameters value="name=Ajax"/>
  <field id="input1"/>
</get>
```

This will send the following request:

```
http://thishost/action?name=Ajax&input1=<val_input1>
```

Where **val_input1** is the current value of the **input1** input widget. The result must be an *XML/Ajax* document that will be parsed.

- make a list sortable:

```
<make_sortable>
  <list id="firstlist"/>
  <list id="secondlist"/>
</make_sortable>
```

Here **firstlist** and **secondlist** are **id** of *UL* elements. It is possible to specified as many list id as needed. A drag and drop is then possible for all elements in those lists. It is then possible to reference such list by passing the list id as a field to the template. Items on those list will be serialized and passed to the *AWS* callback. Note that for the serialization to work properly, each *LI* elements must be given the id of the list and then the value we want to pass:

```
<ul id="firstlist">
  <li id="firstlist_red">Red</li>
  <li id="firstlist_green">Green</li>
  <li id="firstlist_blue">Blue</li>
</ul>
```

The serialization will send each value on this list using a multi-valued parameter named **firstlist[]**:

```
http://server?firstlist[]=red&firstlist[]=green&firstlist[]=blue
```

- make a list not sortable:

```
<destroy_sortable>
  <list id="firstlist"/>
  <list id="secondlist"/>
</destroy_sortable>
```

Remove the sortable properly from the specified lists.

- redirect to another URL:

```
<location url="http://thishost/go_there"/>
```

Redirect the browser to the specified URL.

- refresh the current page:

```
<refresh/>
```

Refresh the current page as if the Web Browser refresh button was pressed.

- add a CSS style to a given node:

```
<apply_style id="node_id">
  <attribute id="display" value="none"/>
</apply_style>
```

Add the CSS style *display:none* to the **node_id** element. It is possible to specify multiple attributes if needed.

- make an entry disabled or enabled:

```
<disabled id="item_id" value="true/false"/>
```

- make an entry read-only or writable:

```
<read_only id="item_id" value="true/false"/>
```

- reset a form:

```
<reset id="form_id"/>
```

Here is an example of such XML document:

```
<?xml version="1.0" encoding="UTF-8" ?>
<response>
  <replace id="xml_status_bar">Fill Widgets...</replace>
  <replace id="text1">Response from XML</replace>
  <replace id="text2">Another response for text2</replace>
  <replace id="input1">tag is input1</replace>
  <replace id="input2">tag is input2</replace>
  <select action="add" id="xmlsel" option_value="one" option_content="1"/>
  <select action="add" id="xmlsel" option_value="two" option_content="2"/>
  <select action="add" id="xmlsel" option_value="three" option_content="3"/>
  <select action="select" id="xmlsel" option_value="two"/>
  <radio action="select" id="radio1"/>
  <check action="select" id="check1"/>
  <check action="select" id="check3"/>
  <check action="clear" id="check2"/>
</response>
```

To register an *Ajax* action to a specific tag id a macro can be used. It is named *JS_ACTION* and defined in `ajax_api.tjs`. The usage is similar to what is described in the previous section (see *Basic Ajax support*) except that in this case we use a macron instead of an include file and we do not have to pass the placeholder.

Let's revisit the first example above to use the *XML Ajax* support.

- The AWS/Ajax runtime support:

```
@@INCLUDE@@@ aws.tjs
```

Must be included in every Web pages into the *<head>* tag.

- The AWS/Ajax API:

```
@@INCLUDE@@@ ajax_api.tjs
```

Must be included at least once during an application life-time. It gives access to the *JS_ACTION* macro.

- The widget: a button:

```
<input id="clickme" type="button" value="Clik Me">
```

- The result area: a div:

```
<div id="placeholder">... result here ...</div>
```

- The AWS/Ajax:

```
@_JS_ACTION(onclick, clickme)_@
```

Basically it places an **onclick** attribute (the event) in the *HTML <input>* identified as **clickme** (the action) above. Here is what happen when the button is clicked:

- send the "/onclick$clickme" HTTP request to the server

- asynchronously wait for the XML answer, when received parse the answer and perform the actions according to the *XML* content.

To set the placeholder with "**new text**", the *XML* document returned by the server must be:

```
<?xml version="1.0" encoding="UTF-8" ?>
<response>
  <replace id="placeholder">new text</replace>
</response>
```

If we want also to clear the input field named **field** and to select the radio button named **radio1** we must return:

```
<?xml version="1.0" encoding="UTF-8" ?>
<response>
  <replace id="placeholder">new text</replace>
  <clear id="field"/>
  <radio action="select" id="radio1"/>
</response>
```

This is by far the most flexible solution as it is possible to return, from the server, a structured answer.

A final comment, if the text returned by the server to replace a specific area is an *HTML* fragment, the content must be placed into a *CDATA* tag:

```
<?xml version="1.0" encoding="UTF-8" ?>
<response>
  <replace id="item_id">
    <![CDATA[ *HTML CODE HERE* ]]>
  </replace>
</response>
```

Advanced Ajax

Finally, if this is not enough because you need to use some specific *JavaScript* code, *AWS* provides a macro named *BIND_JS* to add an event to a specific widget, the action being the name of a *JavaScript* routine.

This macro together with the `aws_func_replace.tjs`, `aws_func_clear.tjs` templates and the `JS_ACTION` macro can be used to chain multiple actions. Those templates are the function body used by the corresponding templates `aws_action_replace.tjs`, `aws_action_clear.tjs`.

Let say you want to clear a widget, change the content of another one and calling one of your specific *JavaScript* routine when clicking on a button. It is not possible to have mutiple *onclick* events on the same widget, the solution is the following:

- Create the JavaScript routine to do the job

    For this in the the body of the *clear_replace()* JavaScript routine we place:

    ```
    function clear_replace()
    {
      @@INCLUDE@@ aws_func_replace.tjs (clickme placeholder 4=>field)
      @@INCLUDE@@ aws_func_clear.tjs (area)
      call_this_routine();
    }
    ```

    Then to add the event on the widget:

    ```
    @_BIND_JS(onclick, clickme clear_replace)_@
    ```

Furthermore, it is possible to pass (as the parameter number 20) a routine to call after a specific action to all templates and to the *JS_ACTION* macro. This is another way to chain multiple actions for a single event.

Note that all *AWS/Ajax* templates and the `ajax_api.tjs` file have a set of comments at the start explaining in details the usage of each parameter.

4.8 Web Blocks

The *AWS.Services.Web_Block* hierarchy contains an API useful for keeping context on Web pages. It has been designed to be able to split a Web application into a set of independent blocks that can be put together in the same Web page. The context is then useful as it is passed and known by each individual block. Note that this is different than the session as a session is global to the current Web browser whereas the context can be different for each individual web pages opened.

Instead of parsing a whole page using *AWS.Templates* API the web blocks are registered independently using *AWS.Services.Web_Block.Registry*. The block is registered together with its templates and a callback to use to get user's data for this specific block with the given context.

So using this API, instead of having a set of callbacks returning an *AWS.Response.Data* and where the final rendering is to be done by the client code, we have a set of callbacks that returns a *Translate_Set*. The client just have to fill the set with the data corresponding to the actual request and possibly using the context. The final rendering is done by the provided services in *Web_Block.Registry*.

Note that all Web pages must also be registered into the registry to ensure that the context identification is properly kept. The context identification is injected into the Web pages transparently for the end-user when using *Ajax*.

4.8.1 Web Block example

Let's have a simple example, a page containing a single block with a tag (@_COUNTER_@) which is incremented by one each time it is used. The code can be found in `demos/web_block`.

First create the following HTML fragment and place it into `counter.thtml`:

```
<p>@_COUNTER_@</p>
```

Then create the main page and place it into `page.thtml`. The important part is the @_CTX_WB_@ tag which is passed to the link. This tag is the context identifier, it must be passed to each request. Note that this is automatically done when using the *Ajax* framework (see *Web Block and Ajax*):

```
<html>
  <head>
    <title>Main Page</title>
  </head>
  <body>
    <p>This is the main page, bellow is a simple counter</p>
    <p>@_COUNTER_@</p>
    <a href="/?CTX_WB=@_CTX_WB_@">Next</a>
  </body>
</html>
```

The *Web_Callbacks* package contains the application callbacks:

```
with AWS.Response;
with AWS.Status;
with AWS.Templates;
with AWS.Services.Web_Block.Context;

package Web_Callbacks is

   use AWS;
   use AWS.Services;

   function Main (Request : in Status.Data) return Response.Data;
   --  Main callback which handle the home page

   procedure Counter
     (Request      : in                    Status.Data;
      Context      : not null access Web_Block.Context.Object;
      Translations : in out           Templates.Translate_Set);
   --  The callback handling the counter web block

end Web_Callbacks;
```

Last part is to actually implement the *Counter* callback. Here is a possible implementation making use of the context to keep the counter state:

```
with AWS.Utils;
with AWS.Messages;
with AWS.MIME;
with AWS.Services.Web_Block.Registry;

package body Web_Callbacks is

   -------------
```

```
   -- Counter --
   -------------

   procedure Counter
     (Request      : in                Status.Data;
      Context      : not null access Web_Block.Context.Object;
      Translations : in out            Templates.Translate_Set)
   is
      N : Natural := 0;
   begin
      if Context.Exist ("N") then
         N := Natural'Value (Context.Get_Value ("N"));
      end if;

      N := N + 1;
      Context.Set_Value ("N", Utils.Image (N));

      Templates.Insert
        (Translations, AWS.Templates.Assoc ("COUNTER", N));
   end Counter;

   ----------
   -- Main --
   ----------

   function Main (Request : in Status.Data) return Response.Data is
      URI : constant String := Status.URI (Request);
   begin
      return Web_Block.Registry.Build
        (Key          => URI,
         Request      => Request,
         Translations => Set);
   end Main;

end Web_Callbacks;
```

Finally, we write the main procedure:

```
with Ada.Text_IO;

with AWS.Server;
with AWS.Services.Web_Block.Registry;

with Web_Callbacks;

procedure Web_Block is

   use Ada;
   use AWS;
   use AWS.Services;

   HTTP : AWS.Server.HTTP;

begin
   --  First we register the main page and the counter block

   Services.Web_Block.Registry.Register ("/", "page.thtml", null);
```

```
   Services.Web_Block.Registry.Register
     ("COUNTER", "counter.thtml",
      Web_Callbacks.Counter'Access, Context_Required => True);

   --  Then we just start the server

   Server.Start (HTTP, "web_block", Web_Callbacks.Main'Access);

   Text_IO.Put_Line ("Press Q to terminate.");

   Server.Wait (Server.Q_Key_Pressed);

   Server.Shutdown (HTTP);
end Web_Block;
```

Compile and run the server. Then connect to the server and click on next. The counter will be incremented by one each time.

4.8.2 Web Block and Ajax

The Web Block framework has really been designed to be used with *Ajax*. It is the only way to gain the full power of the Web Block framework.

For the complete code, see *demos/web_block_ajax*.

When using *Ajax* it is not needed to explicitly pass the context identification to every link. This is done automatically by the framework. So the main page will look like this:

```
@@INCLUDE@@ ../../web_elements/javascripts/ajax_api.tjs
<html>
  <head>
    <title>Main Page</title>
    @@INCLUDE@@ ../../web_elements/javascripts/aws.tjs
  </head>
  <body>
    <p>This is the main page, bellow is a simple counter</p>
    @_WIDGET_COUNTER_@
  </body>
</html>
```

The counter widget is on `widget_counter.thtml`:

```
<!-- implementation of a simple counter widget -->
<p><div id="counter">@_COUNTER_@</div></p>
<a id="next" href="/">Next</a>
@_JS_ACTION(onclick, next)_@
```

For the *Ajax* part, see *Ajax*.

We now have one more register call for registering the *next* button *Ajax* callback, and a callback named *Widget_Counter* for displaying the block:

```
Services.Web_Block.Registry.Register
  ("WIDGET_COUNTER", "widget_counter.thtml",
   Web_Callbacks.Widget_Counter'Access);

Services.Web_Block.Registry.Register
```

```
("/onclick$next", "r_widget_counter.txml",
 Web_Callbacks.Onclick_Next'Access,
 Content_Type     => MIME.Text_XML,
 Context_Required => True);
```

The *next Ajax* button is using an XML based response which is defined in `r_widget_counter.txml`:

```
<?xml version="1.0" encoding="UTF-8" ?>
<response>
  <replace id="counter">@_COUNTER_@</replace>
</response>
```

The *Widget_Counter* callbacks just have to set the *COUNTER* tag variable to the corresponding value. This is used to display the block. The *Ajax* callback *Onclick_Next* has to increment the counter and set the *COUNTER* tag variable, a simple implementation is:

```
procedure Onclick_Next
  (Request      : in                 Status.Data;
   Context      : not null access Web_Block.Context.Object;
   Translations : in out             Templates.Translate_Set)
is
   N : Natural := 0;
begin
   if Context.Exist ("N") then
      N := Natural'Value (Context.Get_Value ("N"));
   end if;

   N := N + 1;

   Context.Set_Value ("N", Utils.Image (N));

   Templates.Insert
     (Translations, Templates.Assoc ("COUNTER", N));
end Onclick_Next;
```

The framework will then call *Onclick_Next* when pressing the *Next* button. This routine increments N by one sending back a response based on *r_widget_counter.txml*. Finally, the client browser will parse this XML response and do the corresponding actions.

4.8.3 Web Block and templates2ada

For the complete code, see *demos/web_block_ajax_templates*.

It is possible to use the *Templates_Parser's templates2ada* tool for generating the callbacks register calls. This ensures that all tags on the application Web Pages have a corresponding callback.

The code is almost identical to the standard *Ajax* example above. The main difference is that we need to use a naming convention for the blocks. This way we can generate automatically the corresponding callbacks using a template. A common convention is to add *LAZY_* as prefix for the name of the blocks. With this convention the main page template is:

```
@@INCLUDE@@ ../../web_elements/javascripts/ajax_api.tjs
<html>
  <head>
    <title>Main Page</title>
    @@INCLUDE@@ ../../web_elements/javascripts/aws.tjs
  </head>
```

```html
  <body>
    <p>This is the main page, bellow is a simple counter</p>
    @_LAZY_WIDGET_COUNTER_@
  </body>
</html>
```

We need also modify the standard `templates.tads` as distributed with the *Templates_Parser*. Here is the interesting part:

```
@@SET@@ PACKAGE = WBlocks

...

with AWS.MIME;
with AWS.Services.Web_Block.Registry;
with Web_Callbacks;

@@TABLE@@
with @_PACKAGE_@.@_CAPITALIZE:REPLACE_ALL(\\./_):BASENAME_@;
@@END_TABLE@@

package body @_PACKAGE_@ is

   use AWS;

   package body Lazy is

            Context_Required => True);
           @@END_IF@@
         @@END_TABLE@@
         @@END_TABLE@@
```

```
      end Register;
   end Lazy;
end @_PACKAGE_@;
```

Basically this is to write a register call for every template's tag starting with *LAZY_*. The second section is to write a register call for every *Ajax* event. All callbacks are expected to be in a package named *Web_Callbacks*. It is of course possible to change this template to reference callbacks for blocks and *Ajax* in separate packages. The use of a template here is very flexible.

Now let's parse the application HTML and XML templates and create the corresponding Ada specs and register calls:

```
$ templates2ada -d . -o code.ada -t templates.tada -e .thtml -e .txml
$ gnatchop code.ada
```

Look at the generated code below, it properly register the *Widget_Counter* callback to be used for rendering *LAZY_WIDGET_COUNTER* using the `widget_counter.thtml`. So we have a tight coupling between the code and the template file. If the tag is renamed in the template file the application will not compile anymore. The same is true for *Ajax* callbacks, every *Ajax* action put in a template file needs a corresponding callback in Ada. This greatly helps keeping the application code synchronized:

```
procedure Register is
   use AWS.Services;
begin
   Web_Block.Registry.Register
     ("LAZY_WIDGET_COUNTER",
      "widget_counter.thtml",
      Web_Callbacks.Widget_Counter'Access);
   Services.Web_Block.Registry.Register
     ("/onclick$next",
      WBlocks.R_Widget_Counter.Template,
      Web_Callbacks.Onclick_Next'Access,
      Content_Type    => MIME.Text_XML,
      Context_Required => True);
end Register;
```

In the main, it is just now required to register the Web pages and to call the generated *Register* procedure:

```
Services.Web_Block.Registry.Register ("/", "page.thtml", null);

WBlocks.Lazy.Register;
```

Moreover, an Ada spec containing reference for the tag names is generated for every HTML and XML template file. All tags can be referenced using those specs, it is not needed to use string literal in the application. Again, this ensures that a tag which is renamed or deleted is detected at compilation time. For example the *Widget_Counter* callback can be rewritten as follow:

```
procedure Widget_Counter
  (Request      : in               Status.Data;
   Context      : not null access Web_Block.Context.Object;
   Translations : in out           Templates.Translate_Set)
is
   N : Natural := 0;
begin
   if Context.Exist ("N") then
      N := Natural'Value (Context.Get_Value ("N"));
   end if;
```

```
   Templates.Insert
      (Translations, Templates.Assoc (WBlocks.Widget_Counter.COUNTER, N));
end Widget_Counter;
```

4.9 Web Cross-References

When building an *Ajax* Web applications it is required to give ids to web elements to be able to reference them. It is also quite common to use CSS to give such and such item a specific style. After some time it is quite difficult to keep track of all those ids. Are they all used ? Don't we reference an id that does not exist anymore ?

webxref has been designed to help finding such problems.

The files kinds handled are:

.css, .tcss A CSS (or template CSS file). Ids and classes inside are recorded as CSS definitions.

.xml, .html, .thtml A meta-language document. Ids and classes inside are recorded as referencing a CSS definition and meta-language definition.

.txml An *Ajax* response file. Ids declared inside are recorded as referencing a meta-language definition.

The features are:

cross-references By default *webxref* output all the references to ids and classes.

finding unused items Output the ids/classes that are defined but not used. For example an id declared in a CSS but never referenced into an HTML document or an HTML id never referenced in an *Ajax* response file `.txml` document.

finding undeclared items Output ids/classes that are referenced but never defined. This is for example an id inside an *Ajax* response file which is never defined into an HTML document.

enforcing a naming scheme for ids and classes It can enforce a specific prefix for ids and classes. The id prefix can be based on the filename (using filename's first character and all character before an underscore). This make it less likely to find the same id on multiple files.

Note that all references are in a format recognized by tools like *GPS* and *Emacs*. It is then possible to navigate inside them easily.

All *webxref* options are listed using the *-h* option.

4.10 WebSockets

4.10.1 Introduction to WebSockets

WebSockets are part of HTML5, the API is being standardized by the W3C and the protocol by the IETF (see RFC-6455). It is a bidirectional and full-duplex communication channel between the client and the server. Most Web Browsers are now supporting (at least part) of the WebSocket recommendation. On the client side, the WebSockets are programmed in JavaScript as done for Ajax for example.

A WebSocket is always opened at the request of a client. This can be done on the same port as the main HTTP protocol. This is possible because the initial handshake to open a WebSocket is done in pure HTTP protocol. Past this initial handshake the socket is switching protocol from HTTP to the one called WebSocket protocol.

It is not needed to know the protocol to use the WebSockets, AWS comes with some high level services on the server side and also on the client side.

4.10.2 WebSockets on the client (javascript)

The WebSocket is created on the client side. As there is some differences between Web browsers, AWS provides a wrapper routine to create a WebSocket:

```
ws = AWS.WebSocket.open('ws://localhost:8080/echo');
```

This basically create a WebSocket and contact the local server using port 8080.

This method is declared into `aws.tjs` which must be included:

```
@@INCLUDE@@@ aws.tjs
```

A WebSocket Javascript's object has four method's callbacks:

onopen Called when the WebSocket has been opened. This means that the initial handshake with the server has been accepted. At this point the WebSocket is ready to send and received messages.

onmessage Called for every incoming message. This callback receive a single parameter which is the event. The actual message data can be found in **e.data**.

onclose Called when the WebSocket is closing. This means that the server has sent a close request. After this event it is not possible to send nor receive messages through this WebSocket.

onerror Called when an error has occurred. This can be a lost connection for example. This callback takes a single parameter which is the error message.

AWS comes with default implementation of those callbacks. With the two optional WebSocket constructor parameters it can be configured to fit most needs:

```
ws = AWS.WebSocket.open('ws://localhost:8080/echo', message_id, status_id);
```

message_id The id of the HTML element which will be used to display the incoming messages. This is most of the time the id of a *p* or *div* HTML element.

status_id The id of the HTML element which will be used to display the status and error messages. For example when a connection is closed.

When those default callbacks are not what is needed it is always possible to redefine them:

```
ws.onmessage = function (e) {
  code there
};
```

Likewise for the other events.

4.10.3 WebSockets on the client (Ada)

AWS also supports writing websocket clients directly in Ada. Here is an example:

```
type MySocket is new AWS.Net.WebSocket.Object with null record;
overriding procedure On_Message (Self : in out MySocket; Str : String);
--  You would likely also override On_Error and On_Close

overriding procedure On_Message (Self : in out MySocket; Str : String) is
begin
   Ada.Text_IO.Put_Line ("++ Got message '" & Str & "'");
end On_Message;
```

```
declare
   Socket    : MySocket;
begin
   AWS.Net.WebSocket.Connect (Socket, "ws://localhost:8765");

   --  Send one message
   Socket.Send ("some message");

   --  Then wait for any number of messages from the server. Give up if
   --  no message is available for 2s. If messages become available, the
   --  procedure On_Message will be called.
   while Socket.Poll (Timeout => 2.0) loop
      null;
   end loop;

   Socket.Close ("");
end;
```

You are responsible for checking regularly whether any message has been received from the server.

4.10.4 WebSockets on the server

The first step is to setup the server to dispatch the incoming messages to the proper WebSocket object. For this one needs to inherit from *AWS.Net.WebSocket.Object* and redefine at least two methods *Create* and *On_Message*:

Create This is the constructor that will be used by the server to handle some WebSockets. This constructor will be associated to some URI, see below:

```
function Create
  (Socket  : Socket_Access;
   Request : AWS.Status.Data) return Object'Class;
```

The default constructor creates a WebSocket of type *AWS.Net.WebSocket.Object*. It is not possible to receive events (close, open, error) using such object it is only possible to send messages to the clients.

Here is an example on a custom socket:

```
type MySocket is new Net.WebSocket.Object with null record;

function Create
  (Socket  : Socket_Access;
   Request : AWS.Status.Data) return AWS.Net.WebSocket.Object'Class
is
   --  Note the call to the other version of Create*
   return MySocket'
     (AWS.Net.WebSocket.Object
        (AWS.Net.WebSocket.Create (Socket, Request)) with null record);
end Create;
```

It is also possible to deny the handshake by returning an object from AWS.Net.WebSocket.Handshake_Error.

On_Open This is the callback that will be called when the WebSocket is opened:

```
procedure On_Open
  (Socket : in out Object; Message : String) is null;
```

On_Message This is the callback that will be called for every message sent by the client on the corresponding WebSocket:

```
procedure On_Message
   (Socket : in out Object; Message : String);
```

The first parameter is the WebSocket itself, it is possible to send a message directly by using the associated *Send* method. Note that the default implementation supports the XML based Ajax actions. See see *XML based Ajax* and can be used to redirect simple message to an HTML widget given it's id.

On_Close This is the callback that will be called when the WebSocket is closed:

```
procedure On_Close
   (Socket : in out Object; Message : String) is null;
```

On_Error This is the callback that will be called when an error occurs on the WebSocket:

```
procedure On_Error
   (Socket : in out Object; Message : String) is null;
```

When this is done, the constructor declared above needs to be registered to handle some WebSocket designated by the URI. For example to have this WebSocket handling all URI named */echo*:

```
Net.WebSocket.Registry.Register ("/echo", CB.Create'Access);
```

Where *CB.Create* is the constructor redefined for the new WebSocket class.

The last step is to start the WebSocket server which are needed to handle the incoming messages:

```
Net.WebSocket.Registry.Control.Start;
```

At this point all is setup to have AWS supports WebSockets. Sending messages can be done to a single client or by broadcasting to all clients for a specific URI. To send a message one need to create a *Net.WebSocket.Registry.Recipient* object. For example to broadcast a message to all Web clients having opened the */echo* WebSocket:

```
Rcp : Net.WebSocket.Registry.Recipient :=
      Net.WebSocket.Registry.Create (URI => "/echo");

Net.WebSocket.Registry.Send (Rcp, "A simple message");
```

As we have seen before, this will send a message to clients which will in turn trigger the *onmessage* Javascript method.

It is also possible to send a message to clients from a specific origin by using the *Origin* information:

```
Rcp : Net.WebSocket.Registry.Recipient :=
      Net.WebSocket.Registry.Create (URI => "/echo"; Origin => ".*\\.fr");

Net.WebSocket.Registry.Send (Rcp, "A simple message");
```

The above recipent targets all WebSockets whose URI is *"/echo"* and that have been created from a Web page originating from a Web server running in the *.fr* domain. Note that *URI* and the *Origin* are regular expressions.

The *Origin* value can be used by a server to handle only WebSockets originating from it's own domain. Restricting the origin of the WebSockets can be done with the *WEBSOCKET_ORIGIN* config parameter, see WebSocket_Origin.

USING SOAP

SOAP can be used to implements Web Services. The *SOAP* implementation uses *AWS HTTP* as the transport layer. *SOAP* is platforms and languages independent, to ensure a good inter-operability, *AWS/SOAP* implementation has been validated through http://validator.soapware.org/, the version number listed on this server corresponds to the AWS version string (*AWS.Version*) catenated with the *SOAP* version string (*SOAP.Version*).

This *SOAP* implementation is certainly one with the higher level of abstraction. No need to mess with a serializer, to know what is a payload or be an *XML* expert. All the low level stuffs are completely hidden as the *SOAP* type system has been binded as much as possible to the Ada type system.

The *SOAP* type system has been relaxed to be compatible with *WSDL* based *SOAP* implementation. In these implementations, types are generally (as in the Microsoft implementation) not part of the payload and should be taken from the *WSDL* (Web Services Description Language). *AWS/SOAP* is not *WSDL* compliant at this stage, all such types are binded into the Ada type system as strings. It is up to the programer to convert such strings to the desired type.

5.1 SOAP Client

The *SOAP* client interface is quite simple. Here are the step-by-step instructions to call a *SOAP* Web Service:

- Build the *SOAP* parameters

  As for the *SOAP* servers, the *SOAP* parameters are built using a *SOAP.Parameters.List* object:

  ```
  Params : constant Parameters.List := +I (10, "v1") & I (32, "v2");
  ```

- Build the *SOAP* Payload

  The Payload object is the procedure name and the associated parameters:

  ```
  declare
     Payload : Message.Payload.Object;
  begin
     Payload := Message.Payload.Build ("Add", Params);
  ```

- Call the *SOAP* Web Service

  Here we send the above Payload to the Web Server which handles the Web Service. Let's say that this server is named *myserver*, it is listening on port *8082* and the *SOAPAction* is *soapdemo*:

  ```
  Resp : constant Message.Response.Object'Class :=
           SOAP.Client.Call ("http://myserver:8082/soapdemo", Payload);
  ```

- Retrieve the result

  Let's say that the answer is sent back into the parameter named "myres", to get it:

```
My_Res : constant Integer := SOAP.Parameters.Get (Params, "myres");
```

In the above example we have called a Web Service whose spec could be described in Ada as follow:

```
function Add (V1, V2 : in Integer) return Integer;
--  Add V1 and V2 and returns the result. In SOAP the result is named "myres"
```

5.2 SOAP Server

A *SOAP* server implementation must provides a callback procedure as for standard Web server *Callback procedure*. This callback must checks for the *SOAP* Action URI to handle both standard Web requests and *SOAP* ones. The *SOAPAction* is sent with the HTTP headers and can be retrieved using *AWS.Status.SOAPAction*.

5.2.1 Step by step instructions

Here are the step-by-step instructions to be followed in the *SOAP* callback procedure:

• Retrieve the *SOAP* Payload

The *SOAP* Payload is the *XML* message, it contains the procedure name to be called and the associated parameters:

```
function SOAP_CB (Request : in AWS.Status.Data) return AWS.Response.Data is
   use SOAP.Types;
   use SOAP.Parameters;

   Payload : constant SOAP.Message.Payload.Object :=
               SOAP.Message.XML.Load_Payload (AWS.Status.Payload (Request));
```

AWS.Status.Payload returns the *XML* Payload as sent by the *SOAP* Client. This *XML* Payload is then parsed using *SOAP.Message.XML.Load_Payload* which returns a *SOAP.Message.Payload.Object* object.

• Retrieve the *SOAP* Parameters

The *SOAP* procedure's parameters:

```
Params : constant SOAP.Parameters.List :=
           SOAP.Message.Parameters (Payload);
```

SOAP.Parameters.List is a structure which holds the *SOAP* parameters. Each parameter can be retrieved using a *SOAP.Parameters* API, *SOAP.Parameters*. For example to get the parameter named *myStruc* which is a *SOAP* struct:

```
My_Struct : constant SOAP_Record :=
              SOAP.Parameters.Get (Params, "myStruct");
```

Another example, to get the parameter named *myInt* which is a *SOAP* integer:

```
My_Int : constant Integer := SOAP.Parameters.Get (Params, "myInt");
```

• Implements the Web Service

This is the real job, as for any procedure you can do whatever is needed to compute the result.

- Build the *SOAP* answer

  This is the procedure answer. A *SOAP* answer is built from the *SOAP* Payload and by setting the returned parameters:

```
declare
   Resp        : SOAP.Message.Response.Object;
   Resp_Params : SOAP.Parameters.List;
begin
   Resp := SOAP.Message.Response.From (Payload);

   Resp_Params := +I (My_Int * 2, "answer");

   SOAP.Message.Set_Parameters (Resp, Resp_Params);
```

  This build a response which is a single integer value named *answer* with the value *My_Int * 2*.

- Returns the answer back to the client

  This last step will encode the response object in *XML* and will returns it as the body of an *HTTP* message:

```
return SOAP.Message.Response.Build (Resp);
```

5.2.2 SOAP helpers

There is two ways to help building the *SOAP* callbacks. *AWS* provides a *SOAP* specific callback, the spec is:

```
function SOAP_Callback
  (SOAPAction : in String;
   Payload    : in Message.Payload.Object;
   Request    : in AWS.Status.Data) return AWS.Response.Data;
```

With both solutions exposed below, *AWS* retrieve the *SOAPAction* and the Payload from the *SOAP* request. This is transparent to the user.

- Using Utils.SOAP_Wrapper

  It is possible to dispatch to such callback by using the *SOAP.Utils.SOAP_Wrapper* generic routine:

```
generic
   with function SOAP_CB
            (SOAPAction : in String;
             Payload    : in Message.Payload.Object;
             Request    : in AWS.Status.Data) return AWS.Response.Data;
function SOAP_Wrapper
  (Request : in AWS.Status.Data) return AWS.Response.Data;
--  From a standard HTTP callback call the SOAP callback passed as generic
--  formal procedure. Raise Constraint_Error if Request is not a SOAP
--  request.
```

  For example, from the standard HTTP callback *CB* we want to call *SOAP_CB* for all *SOAP* requests:

```
function SOAP_CB
  (SOAPAction : in String;
   Payload    : in Message.Payload.Object;
   Request    : in AWS.Status.Data) return AWS.Response.Data is
begin
   --  Code here
```

```
end SOAP_CB;

procedure SOAP_Wrapper is new SOAP.Utils.SOAP_Wrapper (SOAP_CB);

function CB (Request : in AWS.Status.Data) return AWS.Response.Data is
   SOAPAction : constant String := Status.SOAPAction (Request);
begin
   if SOAPAction /= "" then
      SOAP_Wrapper (Request);
   else
      ...
```

• Using a SOAP Dispatcher

AWS provides also a *SOAP* specific dispatcher. This dispatcher will automatically calls a standard *HTTP* or *SOAP* callback depending on the request. If *SOAPAction* is specified (i.e. it is a *SOAP* request), the dispatcher will call the *SOAP* callback otherwise it will call the standard *HTTP* callback. This is by far the easiest integration procedure. Using dispatcher the above code will be written:

```
function SOAP_CB
  (SOAPAction : in String;
   Payload    : in Message.Payload.Object;
   Request    : in AWS.Status.Data) return AWS.Response.Data is
begin
   --  Code here
end SOAP_CB;

function CB (Request : in AWS.Status.Data) return AWS.Response.Data is
   SOAPAction : constant String := Status.SOAPAction (Request);
begin
   --  Code here
end CB;

--  In the main procedure

begin
   AWS.Server.Start
     (WS,
      Dispatcher =>
        SOAP.Dispatchers.Callback.Create (CB'Access, SOAP_CB'Access),
      Config     =>
        AWS.Config.Default_Config);
```

The dispatcher is created using *SOAP.Dispatchers.Callback.Create*. This routine takes two parameters, one is the standard HTTP callback procedure and the other is the *SOAP* callback procedure.

USING WSDL

WSDL (Web Service Definition Language) is an *XML* based document which described a set of Web Services either based on *SOAP* or *XML/RPC*. By using a *WSDL* document it is possible to describe, in a formal way, the interface to any Web Services. The *WSDL* document contains the end-point (URL to the server offering the service), the *SOAPAction* (needed to call the right routine), the procedure names and a description of the input and output parameters.

AWS provides two tools to work with *WSDL* documents:

ada2wsdl

> which creates a *WSDL* document from an Ada package spec.

wsdl2aws

> which create the interfaces to use a Web Service or to implement Web Services. With this tool the *SOAP* interface is completely abstracted out, users will deal only with *Ada* API. All the *SOAP* marshaling will be created automatically.

6.1 Creating WSDL documents

Note that this tool is based on *ASIS*.

6.1.1 Using ada2wsdl

ada2wsdl can be used on any Ada spec file to generated a *WSDL* document. The Ada spec is parsed using *ASIS*.

The simplest way to use it is:

```
$ ada2wsdl simple.ads
```

Given the following Ada spec file:

```ada
package Simple is
   function Plus (Value : in Natural) return Natural;
end Simple;
```

It will generate the following *WSDL* document:

```xml
<?xml version="1.0" encoding="UTF-8"?>
<wsdl:definitions name="Simple"
   targetNamespace="http://soapaws/Simple_def/"
   xmlns:tns="http://soapaws/Simple_def/"
   xmlns:soap="http://schemas.xmlsoap.org/wsdl/soap/"
   xmlns:soapenc="http://schemas.xmlsoap.org/soap/encoding/"
```

```
   xmlns:wsdl="http://schemas.xmlsoap.org/wsdl/"
   xmlns:xsi="http://www.w3.org/1999/XMLSchema-instance"
   xmlns:xsd="http://www.w3.org/2001/XMLSchema"
   xmlns:n1="http://soapaws/Standard_pkg/"
   xmlns:n2="http://soapaws/Simple_pkg/">

   <!-- Generated by AWS/Ada2WSDL v1.3.1
        on Tuesday 25 November 2014 at 11:02:44 -->

   <wsdl:message name="Plus_Request">
      <wsdl:part name="Value" type="xsd:int"/>
   </wsdl:message>

   <wsdl:message name="Plus_Response">
      <wsdl:part name="Result" type="xsd:int"/>
   </wsdl:message>

   <wsdl:portType name="Simple_PortType">
      <wsdl:operation name="Plus">
         <wsdl:input message="tns:Plus_Request"/>
         <wsdl:output message="tns:Plus_Response"/>
      </wsdl:operation>
   </wsdl:portType>

   <wsdl:binding name="Simple_Binding" type="tns:Simple_PortType">
      <soap:binding style="rpc"
         transport="http://schemas.xmlsoap.org/soap/http"/>

      <wsdl:operation name="Plus">
         <soap:operation soapAction="Plus"/>
         <wsdl:input>
            <soap:body
               encodingStyle="http://schemas.xmlsoap.org/soap/encoding/"
               namespace="http://soapaws/Simple_def/"
               use="encoded"/>
         </wsdl:input>
         <wsdl:output>
            <soap:body
               encodingStyle="http://schemas.xmlsoap.org/soap/encoding/"
               namespace="http://soapaws/Simple_def/"
               use="encoded"/>
         </wsdl:output>
      </wsdl:operation>
   </wsdl:binding>

   <wsdl:service name="Simple_Service">
      <wsdl:port name="Simple_Port" binding="tns:Simple_Binding">
         <soap:address location="http://.../"/>
      </wsdl:port>
   </wsdl:service>
</wsdl:definitions>
```

The value of the *name* attribute in the *description* node is the name of the *WSDL* document (the name of the Ada spec package). On the *portType* section we have the description of the Ada **Plus** function. Something important to note is that in Ada a function does not have a named return parameter, ada2wsdl use **Result** for the response. Both the input and output parameter are mapped to *SOAP xsd:int* type.

Note that the *SOAP* address generated by default (http://.../) must be edited manually or specified using ada2wsdl's

-a option.

This is of course a very simple example. *ada2wsdl* does support lot more complex specs and will map Ada records, arrays, enumerations, derived types to a corresponding *XML* schema definition. See section below for a description of the mapping.

6.1.2 Ada mapping to WSDL

ada2wsdl parse Ada records, arrays, derived types, enumerations, procedures and functions and generate the corresponding *WSDL* document. In this section we describe the mapping between Ada and *WSDL*.

Integer Mapped to **xsd:int**.

Float Mapped to **xsd:float**.

Long_Float Mapped to **xsd:double**

Long_Long_Float Mapped to **xsd:double**, not supported by SOAP, mapped for convenience but precision cannot be guaranteed.

Boolean Mapped to **xsd:boolean**

String Mapped to **xsd:string**

Unbounded_String Mapped to **xsd:string**, note that Unbounded_String should be used only inside a record for full interoperability. This is a current limitation.

Character Mapped to a Character schema definition:

```
<simpleType name="Character">
  <restriction base="xsd:string">
    <length value="1"/>
  </restriction>
</simpleType>
```

Ada.Calendar.Time Mapped to **xsd:dateTime**

SOAP.Utils.SOAP_Base64 Mapped to **xsd:base64Binary**. *SOAP.Utils.SOAP_Base64* is a subtype of string which is is recognized by *ada2wsdl* to generate the proper SOAP type.

SOAP.Types.Byte Mapped to **xsd:byte**. *SOAP.Types.Byte* is a type which is recognized by *ada2wsdl* to generate the proper SOAP type.

SOAP.Types.Short Mapped to **xsd:short**. *SOAP.Types.Short* is a type which is recognized by *ada2wsdl* to generate the proper SOAP type.

SOAP.Types.Long Mapped to **xsd:long**. *SOAP.Types.Long* is a type which is recognized by *ada2wsdl* to generate the proper SOAP type.

SOAP.Types.Unsigned_Byte Mapped to **xsd:unsignedByte**. *SOAP.Types.Unsigned_Byte* is a type which is recognized by *ada2wsdl* to generate the proper SOAP type.

SOAP.Types.Unsigned_Short Mapped to **xsd:unsignedShort**. *SOAP.Types.Unsigned_Short* is a type which is recognized by *ada2wsdl* to generate the proper SOAP type.

SOAP.Types.Unsigned_Int Mapped to **xsd:unsignedInt**. *SOAP.Types.Unsigned_Int* is a type which is recognized by *ada2wsdl* to generate the proper SOAP type.

SOAP.Types.Unsigned_Long Mapped to **xsd:unsignedLong**. *SOAP.Types.Unsigned_Long* is a type which is recognized by *ada2wsdl* to generate the proper SOAP type.

Derived types Mapped to a type schema definition:

```ada
type Number is new Integer;
```

is defined as:

```xml
<simpleType name="Number" targetNamespace="http://soapaws/WSDL_C_pkg/">
  <restriction base="xsd:int"/>
</simpleType>
```

Derived types with constraints Mapped to a type schema definition with minInclusive and maxInclusive attributes:

```ada
type Number is new Integer range 1 .. 9345;
```

is defined as:

```xml
<simpleType name="Number" targetNamespace="http://soapaws/WSDL_C_pkg/">
  <restriction base="xsd:int">
    <xsd:minInclusive value=" 1"/>
    <xsd:maxInclusive value=" 9345"/>
  </restriction>
</simpleType>

Or for a string::

.. highlight:: ada

type Code is String (1 .. 10);
```

is defined as:

```xml
<simpleType name="Code" targetNamespace="http://soapaws/WSDL_C_pkg/">
  <xsd:restriction base="xsd:string">
    <xsd:Length value="10"/>
  </xsd:restriction>
</simpleType>
```

User's types Mapped to a type schema definition with minInclusive and maxInclusive attributes:

```ada
type Small is range 1 .. 10;
```

is defined as:

```xml
<simpleType name="Small" targetNamespace="http://soapaws/WSDL_C_pkg/">
  <restriction base="xsd:byte">
    <xsd:minInclusive value=" 1"/>
    <xsd:maxInclusive value=" 10"/>
  </restriction>
</simpleType>
```

Modular types Mapped to an unsigned type with an optional maxInclusive attribute:

```ada
type Count is mod 14;
```

is defined as:

```xml
<simpleType name="Count" targetNamespace="http://soapaws/WSDL_C_pkg/">
  <xsd:restriction base="xsd:unsignedByte">
    <xsd:maxInclusive value=" 13"/>
```

```
    </xsd:restriction>
</simpleType>
```

Enumerations Mapped to an enumeration schema definition. For example:

```
type Color is (Red, Green, Blue);
```

is defined as:

```
<simpleType name="Color">
  <restriction base="xsd:string">
    <enumeration value="Red"/>
    <enumeration value="Green"/>
    <enumeration value="Blue"/>
  </restriction>
</simpleType>
```

Records Mapped to a struct schema definition. For example:

```
type Rec is record
   A : Integer;
   B : Float;
   C : Long_Float;
   D : Character;
   E : Unbounded_String;
   F : Boolean;
end record;
```

is defined as:

```
<complexType name="Rec">
  <all>
    <element name="A" type="xsd:int"/>
    <element name="B" type="xsd:float"/>
    <element name="C" type="xsd:double"/>
    <element name="D" type="tns:Character"/>
    <element name="E" type="xsd:string"/>
    <element name="F" type="xsd:boolean"/>
  </all>
</complexType>
```

Arrays Mapped to an array schema definition. For example:

```
type Set_Of_Rec is array (Positive range <>) of Rec;
```

is defined as:

```
<xsd:complexType name="Set_Of_Rec">
  <xsd:sequence>
    <xsd:element name="x" type="n1:Rec"
         minOccurs="0" maxOccurs="unbounded"/>
  </xsd:sequence>
</xsd:complexType>
```

A SOAP encoded format can be generated with the -sea option:

> **<complexType name="Set_Of_Rec">**
>
> > **<complexContent>**

           <restriction base="soap-enc:Array"> <attribute   ref="soap-enc:arrayType"
              wsdl:arrayType="tns:Rec[]"/>

           </restriction>

         </complexContent>

      </complexType>

Array inside a record This part is a bit delicate. A record field must be constrained but a *SOAP* arrays is most of the time not constrained at all. To support this *AWS* use a safe access array component. Such a type is built using a generic runtime support package named *SOAP.Utils.Safe_Pointers*. This package implements a reference counter for the array access and will release automatically the memory when no more reference exists for a given object.

For example, let's say that we have an array of integer that we want to put inside a record:

```ada
type Set_Of_Int is array (Positive range <>) of Integer;
```

The first step is to create the safe array access support:

```ada
type Set_Of_Int_Access is access Set_Of_Int;

package Set_Of_Int_Safe_Pointer is
  new SOAP.Utils.Safe_Pointers (Set_Of_Int, Set_Of_Int_Access);
```

Note that the name *Set_Of_Int_Safe_Pointer* (*<type>_Safe_Pointer*) is mandatory (and checked by `ada2wsdl`) to achieve interoperability with `wsdl2aws`. *Working with WSDL documents*.

From there the safe array access can be placed into the record:

```ada
type Complex_Rec is record
   SI : Set_Of_Int_Safe_Pointer.Safe_Pointer;
end record;
```

To create a Safe_Pointer given a *Set_Of_Int* one must use *Set_Of_Int_Safe_Pointer.To_Safe_Pointer* routine. Accessing individual items is done with *SI.Item (K)*.

These Ada definitions are fully recognized by `ada2wsdl` and will generate standard array and record *WSDL* definitions as seen above:

```xml
<xsd:complexType name="Set_Of_Int">
  <xsd:sequence>
    <xsd:element name="x" type="xsd:int"
        minOccurs="0" maxOccurs="unbounded"/>
  </xsd:sequence>
</xsd:complexType>

<complexType name="Complex_Rec">
  <all>
    <element name="SI" type="tns:Set_Of_Int"/>
  </all>
</complexType>
```

Array as routine parameter When an array is passed as parameter to a *SOAP* routine it is also require to create a corresponding Safe_Pointer when using *Document/Literal* binding and using a user's type package (see *-types* and '-*spec wsdl2aws* options). This is needed for the *AWS* generated code to handle this routine. Even if required in a very specific case it is never an error to declare such Safe_Pointer for an array.

For example:

```
type Set_Of_Int is array (Positive range <>) of Integer;

procedure Call (Values : Set_Of_Int);
```

Then the following declarations are required:

```
type Set_Of_Int_Access is access Set_Of_Int;

package Set_Of_Int_Safe_Pointer is
   new SOAP.Utils.Safe_Pointers (Set_Of_Int, Set_Of_Int_Access);
```

6.1.3 ada2wsdl

```
Usage: ada2wsdl [options] ada_spec
```

ada2wsdl options are:

-a url Specify the *URL* for the Web Server address. Web Services will be available at this address. A port can be specified on the *URL*, *http://server[:port]*. The default value is *http://.../*.

-f Force creation of the *WSDL* file. Overwrite exiting file with the same name.

-doc Generate document's style binding (default is RPC)

-lit Generate literal's style binding (default is encoded)

-I path Add path option for the *ASIS* compilation step. This option can appear any number of time on the command line.

-n name Specify the schema name space root name. The default value is "soapaws".

-noenum Do not generate *WSDL* representation for Ada enumerations, map them to standard string. *Ada mapping to WSDL*.

-sea Generate SOAP encoded format for array definitions. This option is kept for compatibility reason, but the schema based definition for arrays is recommended for better interoperability.

-o file Generate the *WSDL* document into file.

-P proj The project file to use for building the spec.

-q Quiet mode (no output)

-s name Specify the Web Service name for the *WSDL* document, by default the spec package's name is used.

-t path Specify the path to the tree file directory to use. This is needed when using a project file the object directory is not the current directory.

-d Do not generate date/time in WSDL.

-v Verbose mode, display the parsed spec.

6.1.4 ada2wsdl limitations

- Do not handle constrained arrays into a records.

- Unbounded_String are supported with full interoperability only inside a record.

- Only unconstrained arrays are supported

- Arrays with multiple dimensions not supported

6.1. Creating WSDL documents   **69**

6.2 Working with WSDL documents

6.2.1 Client side (stub)

This section describe how to use a Web Service. Let's say that we want to use the Barnes & Noble Price Quote service. The WSDL document for this service can be found at http://www.xmethods.net/sd/2001/BNQuoteService.wsdl. In summary this document says that there is a service named *getPrice* taking as input a string representing the ISBN number and returning the price as floating point.

The first step is to generate the client interface (stub):

```
$ wsdl2aws -noskel http://www.xmethods.net/sd/2001/BNQuoteService.wsdl
```

This will create many files, the interesting one at this point is `bnquoteservice-client.ads`, inside we have:

```
function getPrice (isbn : in String) return Float;
--  Raises SOAP.SOAP_Error if the procedure fails
```

Let's call this service to find out the price for *The Sword of Shannara Trilogy* book:

```
with Ada.Text_IO;
with BNQuoteService.Client;

procedure Price is
   use Ada;

   ISBN : constant String := "0345453751";
   --  The Sword of Shannara Trilogy ISBN

   package LFIO is new Text_IO.Float_IO (Float);

begin
   Text_IO.Put_Line ("B&N Price for The Sword of Shannara Trilogy");
   LFIO.Put (BNQuoteService.Client.getPrice (ISBN), Aft => 2, Exp => 0);
end Price;
```

That's all is needed to use this Web Service. This program is fully functional, It is possible to build it and to run it to get the answer.

6.2.2 Server side (skeleton)

Building a Web Service can also be done from a *WSDL* document. Let's say that you are Barnes & Noble and that you want to build Web Service *getPrice* as described in the previous section.

You have created the *WSDL* document to specify the service spec. From there you can create the skeleton:

```
$ wsdl2aws -nostub http://www.xmethods.net/sd/2001/BNQuoteService.wsdl
```

This will create many files, the interesting one here is `bnquoteservice-server.ads`, inside we have:

```
Port : constant := 80;

generic
   with function getPrice (isbn : in String) return Float;
function getPrice_CB
  (SOAPAction : in String;
```

```
   Payload    : in SOAP.Message.Payload.Object;
   Request    : in AWS.Status.Data) return AWS.Response.Data;
```

This is a *SOAP AWS*'s callback routine that can be instantiated with the right routine to retrieve the price of a book
given its ISBN number. A possible implementation of such routine could be:

```
function getPrice (isbn : in String) return Float is
begin
   if isbn = "0987654321" then
      return 45.0;
   elsif ...
end getPrice;

function SOAP_getPrice is new BNQuoteService.Server.getPrice_CB (getPrice);
```

SOAP_getPrice is a *SOAP AWS*'s callback routine (i.e. it is not a standard callback). To use it there is different
solutions:

Using SOAP.Utils.SOAP_Wrapper This generic function can be used to translate a standard callback based on
AWS.Status.Data into a *SOAP* callback routine:

```
function getPrice_Wrapper is new SOAP.Utils.SOAP_Wrapper (SOAP_getPrice);
```

The routine *getPrice_Wrapper* can be used as any other AWS's callback routines. Note that inside this wrapper
the *XML* payload is parsed to check the routine name and to retrieve the *SOAP* parameters. To call this routine
the payload needs to be parsed (we need to know which routine has be invoked). In this case we have parsed the
XML payload twice, this is not efficient.

Building the wrapper yourself This solution is more efficient if there is many *SOAP* procedures as the payload is
parsed only once:

```
function CB (Request : in Status.Data) return Response.Data is
   SOAPAction : constant String := Status.SOAPAction (Request);
   Payload    : constant SOAP.Message.Payload.Object :=
     SOAP.Message.XML.Load_Payload
       (AWS.Status.Payload (Request), Schema => BNQuoteService.Schema);
   Proc       : constant String :=
     SOAP.Message.Payload.Procedure_Name (Payload);
begin
   if SOAPAction = "..." then

      if Proc = "getPrice" then
         return SOAP_getPrice (SOAPAction, Payload, Request);
      elsif ...
         ...
      end if;

   else
      ...
   end if;
```

Note that the port to be used by the AWS server is described into the server spec.

6.2.3 wsdl2aws

```
Usage: wsdl2aws [options] <file|URL>
```

It is possible to pass a *WSDL* file or direct `wsdl2aws` to a *WSDL* document on the Web by passing it's *URL*.

wsdl2aws options are:

-q Quiet mode (no output)

-d Do not generate date/time in Ada comment.

-debug Generate debug code. Will output some information about the payload to help debug a Web Service.

-a Generate using Ada style names. For example *getPrice* will be converted to *Get_Price*. This formatting is done for packages, routines and formal parameters.

-f Force creation of the file. Overwrite any exiting files with the same name.

-e URL Specify the default endpoint to use instead of the one found in the WSDL document.

-s Skip non supported *SOAP* routines. If *-s* is not used, *wsdl2aws* will exit with an error when a problem is found while parsing the *WSDL* document. This option is useful to skip routines using non supported types and still be able to compile the generated files.

-o name Specify the name of the local *WSDL* document. This option can be used only when using a Web *WSDL* document (i.e. passing an URL to *wsdl2aws*).

-p name Specify a name prefix for all SOAPActions defined in the *WDSL*. This option can be used when multiple WSDL generated callback are to be used together and some of the *WSDL* may have the same name.

-doc Handle document style binding as RPC ones. This is sometimes needed because some *WSDL* document specify a document style binding even though the service behave like an RPC one.

-v Verbose mode, display the parsed spec.

-v -v Verbose mode, display the parsed spec and lot of information while parsing the *WSDL* document tree.

-wsdl Add *WSDL* document as comment into the generated root unit.

-cvs Add CVS Id tag in every generated file.

-nostub Do not generated stubs, only skeletons are generated.

-noskel Do not generated skeletons, only stubs are generated.

-cb Generate a *SOAP* dispatcher callback routine for the server. This dispatcher routine contains the code to handle all the operations as described in the *WSDL* document. You need also to specify the *-spec* and/or *-types* options, see below.

-x operation Add *operation* to the list of *SOAP* operations to skip during the code generation. It is possible to specify multiple *-x* options on the command line.

-spec spec Specify the name of the spec containing the Ada implementation of the *SOAP* routines. This is used for example by the *-cb* option above to instantiate all the server side *SOAP* callbacks used by the main *SOAP* dispatcher routine. If *-types* is not specified, the type definitions are also used from this spec.

-types spec Specify the name of the spec containing the Ada types (record, array) used by *SOAP* routines specified with option *-spec*. If *-spec* is not specified, the spec definitions are also used from this spec.

-main filename Specify the name of the server's procedure main to generate. If file `<filename>.amt` (Ada Main Template) is present, it uses this template file to generate the main procedure. The template can reference the following variable tags:

SOAP_SERVICE The name of the service as described into the *WSDL* document. This tag can be used to include the right units:

```
with @_SOAP_SERVICE_@.Client;
with @_SOAP_SERVICE_@.CB;
```

SOAP_VERSION The AWS's SOAP version.

AWS_VERSION The AWS's version.

UNIT_NAME The name of the generated unit. This is the name of the procedure that will be created:

```
procedure @_UNIT_NAME_@ is
begin
   ...
```

-n name Specify the schema name space root name. The default value is "soapaws".

-proxy name|IP Use this proxy to access the *WSDL* document and generate code to access to these Web Services via this proxy. The proxy can be specified by its DNS name or IP address.

-pu name User name for the proxy if proxy authentication required.

-pp password User password for the proxy if proxy authentication required.

-timeouts [timeouts | connect_timeout,send_timeout,receive_timeout] Set the timeouts for the SOAP connection. The timeouts is either a single value used for the connect, send and receive timeouts or three values separated by a colon to set each timeout independently.

6.2.4 wsdl2aws behind the scene

The *wsdl2aws* tool read a *WSDL* document and creates a root package and a set of child packages as described below:

<root> This is the main package, it contains eventually the full *WSDL* in comment and the description of the services as read from the *WSDL* document.

<NS>.<type>_type_pkg Contains all the type definitions for non standard Ada types. In these packages we find for example the definition of the records and the operation to convert them to/from SOAP objects. The types defined here have possible constraints like range attribute and/or Dynamic_Predicate aspects for Pattern and/or Length WSDL attribute.

The root package <NS> is the name-space of the actual type. This ensure that no type name clash will happen. Those packages are generally not directly withed.

<root>.Types This package contains the definitions of the types which are not *SOAP* base types. We find here the definitions of the *SOAP* structs and arrays with routines to convert them between the Ada and *SOAP* type model. A subtype definition is also created for every routine's returned type. In fact, all definitions here are only alias or renaming of types and/or routines generated in other packages rooted with a name-space as described above. This package is the one that user's should import to gain the visibility of types definitions.

This package also contains the schema object which must be used when calling a Web service or parsing a payload.

<root>.Client All spec to call Web Services.

<root>.Server All spec to build Web Services. These specs are all generic and must be instantiated with the right routine to create the web services.

<root>.CB The *SOAP* dispatcher callback routine.

6.2.5 wsdl2aws limitations

It is hard to know all current limitations as the *WSDL* and *SOAP* world is quite complex. We list there all known limitations:

- Some *SOAP* base types are not supported : *date, time, xsd:hexBinary, decimal*. All these are easy to add (except decimal), it is just not supported with the current version.

- Multi-dimension arrays are not supported.

- abstract types are not supported.

- SOAP MIME attachments are not supported.

- WSDL type inheritance not supported.

- The Document/Encoded SOAP messages' style is not supported

- complexType with xs:choice are only supported with a single occurence of each choice.

6.2.6 awsascb

The awsascb (AWS Aggregate Server Callback) tool can be used to aggregate multiple SOAP callback together. That is, after generated multiple SOAP callback with wsdl2aws it may be needed to create a single server handling all the services. This tools is designed for this.

```
Usage: awsascb <root1> <root2>
```

This is no option to for this tool. The *root* parameters are the *wsdl2aws* generated root service name unit. This tool generates a unit named *agg_server_cb* which contains a SOAP callback and a dispatcher to be used by the server main. Here is the spec:

```ada
--  DO NOT EDIT : generated by awsasc

with AWS.Response;
with AWS.Status;

with SOAP.Dispatchers.Callback;
with SOAP.Message.Payload;
with SOAP.WSDL.Schema;

package Agg_Server_CB is

   use AWS;
   use SOAP;

   pragma Style_Checks (Off);

   type Handler is new SOAP.Dispatchers.Callback.Handler with null record;

   overriding function Schema
     (Dispatcher : Handler;
      SOAPAction : String)
      return WSDL.Schema.Definition;

   function Create
     (HTTP_Callback : AWS.Response.Callback) return Handler;
   --  Returns an handler whose SOAP_Callback is the one below
```

```
   function SOAP_CB
     (SOAPAction : String;
      Payload    : Message.Payload.Object;
      Request    : AWS.Status.Data)
      return Response.Data;

end Agg_Server_CB;
```

And following is an example on using such generated aggregate server callback from a server's main:

```
   WS   : Server.HTTP;
   Conf : Config.Object;
   Disp : Agg_Server_CB.Handler;

begin
   Config.Set.Server_Port (Conf, 0);

   Disp := Agg_Server_CB.Create (HTTP_CB'Access);

   AWS.Server.Start (WS, Disp, Conf);
```

6.3 Using ada2wsdl and wsdl2aws together

Using both tools together is an effective way to build rapidely a *SOAP* server. It can be said that doing so is quite trivial in fact. Let's take the following spec:

```
package Graphics is

   type Point is record
      X, Y : Float;
   end record;

   function Distance (P1, P2 : in Point) return Float;
   --  Returns the distance between points P1 and P2

end Graphics;
```

We do not show the body here but we suppose it is implemented. To build a server for this service it is as easy as:

```
$ ada2wsdl -a http://localhost:8787 -o graphics.wsdl graphics.ads
```

The server will be available on localhost at port 8787:

```
$ wsdl2aws -cb -main server -types graphics graphics.wsdl
$ gnatmake server -largs ...
```

Options

-cb is to create the *SOAP* dispatcher callback routine,

-main server to generate the main server procedure in `server.adb`,

-types graphics to use `graphics.ads` to get references from user's spec (reference to *Graphics.Point* for example).

WORKING WITH MAILS

7.1 Sending e-mail

AWS provides a complete API to send e-mail using *SMTP* protocol. You need to have access to an SMTP server to use this feature. The API covers sending simple mail with text message and/or with *MIME* attachments (base64 encoded). Here are the steps to send a simple e-mail:

- Initialize the SMTP server

```
SMTP_Server : SMTP.Receiver :=
                SMTP.Client.Initialize ("smtp.hostname");
```

Here *AWS* uses the default SMTP port to create an SMTP mail server but it is possible to specify a different one. The hostname specified must be a valid SMTP server.

- Send the e-mail

To send an e-mail there is many different API. Let's send a simple text mail:

```
Status : SMTP.Status;

SMTP.Client.Send
  (SMTP_Server,
   From    => SMTP.E_Mail ("Pascal Obry", "p.obry@wanadoo.fr"),
   To      => SMTP.E_Mail ("John Doe", "john.doe@here.com"),
   Subject => "About AWS SMTP protocol",
   Message => "AWS can now send mails",
   Status  => Status);
```

Here Status will contain the SMTP returned status.

- Check that everything is ok

Using above status data it is possible to check that the message was sent or not by the server. The status contain a code and an error message, both of them can be retrieved using specific routines, see *AWS.SMTP*. It is also possible to check that the call was successful with *SMTP.Is_Ok* routine:

```
if not SMTP.Is_Ok (Status) then
   Put_Line ("Can't send message: " & SMTP.Status_Message (Status));
end if;
```

In the above example, the message content was given as a string but it is possible to specify a disk file. *AWS* can also send MIME messages either from disk files or with in memory base64 encoded binary data. The API provides also a way to send messages to multiple recipients at the same time and to send messages with alternative contents (text and

HTML for example). These features are not described here, complete documentation can be found on the spec see *AWS.SMTP* and *AWS.SMTP.Client*.

7.2 Retrieving e-mail

AWS provides an API to retrieve e-mails from a *POP* mailbox. *POP* stands for *Post Office Protocol* and is the main protocol used by Internet Service Providers around the world. *IMAP* is another well known protocol in this area but it is not supported by *AWS*.

We describes here the *POP* API. For a complete description see *AWS.POP*.

- Opening the mailbox

  The first step is to authenticate using a user name and password. *AWS* supports two methods one called *Clear_Text* which is the most used and another one *APOP* which is more secure but almost not supported by *ISP* for the moment (and will probably never be supported as a more secure protocol named *SPA* -Secure Password Authentication- could be used instead):

  ```
  Mailbox : POP.Mailbox :=
              POP.Initialize ("pop.hostname", "john.does", "mysuperpwd");
  ```

  The default Authentication method is *Clear_Text*.

- Getting mailbox information

  When the connection is opened it is possible to get information about the mailbox like the number of messages or the total number of bytes in the mailbox:

  ```
  N     : constant Natural := POP.Message_Count (Mailbox);

  Bytes : constant Natural := POP.Size (Mailbox);
  ```

- Retreiving individual e-mail

  Each message is numbered starting from 1. A function named *Get* will return a message given its mailbox's number:

  ```
  Message : constant POP.Message := POP.Get (Mailbox, 2, Remove => True);
  ```

  Remove can be set to *False* for the message to stay on the mailbox. The default value is *False*.

- Iterating through the mailbox content

  Another way to retreive message is by using an iterator:

  ```
  procedure Print_Subject
    (Message : in     POP.Message
     Index   : in     Positive;
     Quit    : in out Boolean) is
  begin
   Text_IO.Put_Line (POP.Subject (Message));
  end Print_Message;

  procedure Print_All_Subjects is new POP.For_Every_Message (Print_Subject);

  ...

  Print_All_Subjects (Mailbox, Remove => True);
  ```

It exists a set of routines on a *POP.Message* object to get the subject the content, the date or any headers. It is also possible to work with attachments. See point below.

- Working with attachments

  A message can have a set of *MIME* attachments. The number of attachments can be retrieved using *Attachment_Count*:

```
Message : constant POP.Message := ...;

A_Count : constant Natural := POP.Attachment_Count (Message);
```

As for messages it is possible to get a single attachment using its index in the message or by using an iterator:

```
First_Attachment : constant POP.Attachment := POP.Get (Message, 1);

procedure Write_Attachment
   (Attachment : in      POP.Attachment
    Index      : in      Positive;
    Quit       : in out Boolean) is
begin
   POP.Write (Attachment, Directory => ".");
end Print_Message;

procedure Write_All_Attachments is
  new POP.For_Every_Attachment (Write_Attachment);

...

Write_All_Attachments (Message);
```

It is also possible to retrieve the attachment's filename, the content as a memory stream. See *AWS.POP*.

- Closing the connection

```
POP.Close (POP_Server);
```

LDAP

AWS provides a complete API to retrieve information from LDAP servers. Note that there is no support for updating, modifying or deleting information only to read information from the server.

The *AWS/LDAP* implementation is based on *OpenLDAP*. To build an LDAP application you need to link with the `libldap.a` library. This library is built by *AWS* on Windows based system and will use the `wldap32.dll` as provided with Windows NT/2000/XP. On UNIX based systems, you must install properly the *OpenLDAP* package.

The steps required to read information from an LDAP server are:

Initialize the LDAP directory We open a connection:

```
declare
   Directory : LDAP.Client.Directory;
begin
   Directory := LDAP.Client.Init (Host);
```

Host is the hostname where the LDAP directory is running. It is possible to specify the port if the LDAP server does not use the default one.

Bind to the LDAP server This step is the way to pass a login/password if the LDAP server required an authentication. If not, the login/password must be empty strings:

```
LDAP.Client.Bind (Directory, "", "");
```

Do the search For the search you must specify the base name, a filter, the scope and a set of attributes to retrieve:

```
Response_Set := LDAP.Client.Search
   (Directory, Base_DN, Filter, LDAP.Client.LDAP_Scope_Subtree,
LDAP.Client.Attributes ("cn", "sn", "telephonenumber"));
```

Attributes The set of attributes to retrieve from the directory.

Filter A set of values for some attributes. A filter is <attribute_name>=<value> where value can contain '*' at the end. For example "(cn=DUPON*)" will look for all entries where the common name is starting by the string "DUPON".

Scope

> Define how far in the hierarchical directory the search will operate. It is either one level, all subtrees or on the base of the tree.

For more information see *AWS.LDAP.Client*.

Iterate through the response set For this there is two iterators. *First_Entry*/*Next_Entry* or the generic high level iterator *For_Every_Entry*:

```
declare
  Message : LDAP.Client.LDAP_Message;
begin
  Message := LDAP.Client.First_Entry (Directory, Response_Set);

  while Message /= LDAP.Client.Null_LDAP_Message loop
    Do_Job (Message);

    Message := LDAP.Client.Next_Entry (Directory, Message);
  end loop;
end;
```

Read attributes for each entry Each entry has an associated set of attributes. To retrieve attributes values there is two iterators. *First_Attribute* / *Next_Attribute* or the generic high level iterator *For_Every_Attribute*:

```
declare
  BER  : aliased LDAP.Client.BER_Element;
  Attr : constant String := LDAP.Client.First_Attribute
           (Directory, Message, BER'Unchecked_Access);
begin
  Do_Job (Attr);

  loop
    declare
      Attr : constant String := LDAP.Client.Next_Attribute
               (Directory, Message, BER);
    begin
      exit when Attr = "";
      Do_Job (Attr);
    end;
  end loop;
end;
```

Cleanup At the end of the processing it is important to release memory associated with LDAP objects:

```
LDAP.Client.Free (Message);
LDAP.Client.Unbind (Directory);
```

See *AWS.LDAP.Client* for all high level supported API and documentation.

Note that for complete information about *AWS/LDAP* you you should read an LDAP API description. *AWS/LDAP* is only a binding and follow the LDAP API closely.

JABBER

AWS support part of the Jabber protocol. At this stage only two kind of messages are supported:

- Presence

  To check the presence status of a specific JID (Jabber ID)

- Message

  To send messages to a specific JID (Jabber ID)

Note that if you want an application to check the presence or send message to users it is recommended to create a specific Jabber ID on the server for this application and ask users to accept this specific user to check their presence status.

9.1 Jabber presence

To check for the presence of another JID you must first have the right to do so. The jabber server won't let you see presence of another JID unless the JID have permitted you to see its presence.

- First declare the server and status objects:

```
Server : AWS.Jabber.Server;
Status : AWS.Jabber.Presence_Status;
```

- Connect to the server, you must have an account created and must know the login and password:

```
AWS.Jabber.Connect
   (Server, "jabber.domain.org", "joe", "mysuperpwd");
```

- Then, to check the presence of user "john":

```
AWS.Jabber.Check_Presence
   (Server, "john@jabber.domain.org", Status);
```

- Then, you just have to close the server:

```
AWS.Jabber.Close (Server);
```

9.2 Jabber message

To send a message to a specific JID, you must connect to the server as above and close the server when you don't need to communicate with it anymore. The only different part is to send the message, here is an example:

```
Send_Message
  (Server,
  JID     => "john@jabber.domain.org",
  Subject => "Hello there!",
  Content => "Are you using AWS ?");
```

RESOURCES

AWS support embedded resources. It means that it is possible to build a fully self dependent executable. This is useful when distributing a server. The server program contains the code but also the images (*PNG*, *JPEG*, *GIF*), the templates, the *HTML* pages... more generally any file the Web Server must serve to clients.

10.1 Building resources

To embed the files into the executable you must build a resource tree. This task is greatly simplified using `AWSRes` tool. For example let's say that you want to build a simple server with a single page containing some text and one PNG image. The text is handled directly in the callback procedure and contain a reference to the image `logo.png`. To build the resource tree:

```
$ awsres logo.png
```

This will create a set of packages whose root is the unit *res* by default. The resource tree is created. See *awsres tool* for the complete AWS's usage description.

awsres can also compress the resource files. This can be done by using *awsres*'s -*z* option. Compressed resources are handled transparently. If the Web client supports compression the resource is sent as-is otherwise a decompression stream will be created for the resource to be decompressed on-the-fly while sending it.

10.2 Using resources

This is really the simplest step. The resource tree must be linked with your executable, to do so you just have to 'with' the resource tree root into one of your program unit. This will ensure that the resource tree will be compiled and linked into the executable. *AWS* and *Templates_Parser know* about resource files and will pick them up if available.

Note that this is transparent to users. It is possible to build the very same server based on standard files or resources files. The only change in the code is to 'with' or not the resource tree.

Note that *AWS* supports only a single resource tree. If more than one resource tree is included into a program only one will be seen.

10.3 Stream resources

Users can build a response directly from a stream. In this case the callback answer is built using *AWS.Response.Stream*. It creates a resource object whose operations have been inherited from *AWS.Resource.Stream.Stream_Type* and redefined by the user. So the *Read* operation can dynamically create the result stream data, the *End_Of_File* operation must

returns *True* when the stream data is out and so on. This feature is useful to let users completely create and control dynamically *AWS*'s response content.

See *AWS.Resources.Streams*.

10.4 awsres tool

AWSRes is a tool to build resource files. It creates a root package named `res` by default and a child package for each resource file:

```
Usage: awsres [-hopqrRuz] file1/dir1 [-uz] [file2/dir2...]
```

-a packages are named after the actual filenames

-h Display help message.

-o Specify the output directory, by default it is the current directory.

-p name Append the specified prefix to the resource names.

-q Quiet mode.

-R Activate recursive behavior. In this mode `awsres` will parse recursively all subdirectories. If a directory is specified on the command line then all files in this directory and sub-directories will be added. If a file (possibly a pattern) is specified on the command line then only files matching in directroy and sub-directories will be added.

-r name Set the root unit name. Default is *res*.

-u Add following files as uncompressed resources.

-z Add following files as compressed resources.

ELEVEN

STATUS PAGE

The status page gives information about the *AWS* internal status. For example it returns the server socket ID, the number of simultaneous connection, the number of time a connection has been used...

To display the information *AWS* use a template file. The template file (default is **aws_status.thtml**) is an *HTML* file with some specific tags recognized by the parser. For more information about how the template parser works, please look for the template parser documentation distributed with *AWS*.

Here are the tag variables recognized by *AWS* status page:

ABORTABLE_V (vector tag)   A list of boolean. One for each connection. True means that this connection can be aborted if none is available. This is to be inserted in a template table.

ACCEPT_QUEUE_SIZE   see *Configuration options*.

ACCEPTOR_LENGTH   Number of sockets in the internal socket set.

ACTIVITY_COUNTER_V (vector tag)   A list of natural. One for each connection. This is the number of request the connection has answered. This counter is reset each time the connection is closed. In other word this is the number of request a keep-alive connection has processed.

ACTIVITY_TIME_STAMP_V (vector tag)   A list of date. One for each connection. This is the time of the latest request answered.

ADMIN   URI to the administrative page.

CASE_SENSITIVE_PARAMETERS   see *Configuration options*.

CHECK_URL_VALIDITY   see *Configuration options*.

CLEANER_CLIENT_DATA_TIMEOUT   see *Configuration options*.

CLEANER_CLIENT_HEADER_TIMEOUT   see *Configuration options*.

CLEANER_SERVER_RESPONSE_TIMEOUT   see *Configuration options*.

CLEANER_WAIT_FOR_CLIENT_TIMEOUT   see *Configuration options*.

CURRENT_CONNECTIONS   Number of current connections to the server.

ERROR_LOG (boolean tag)   This is set to true if error logging is active.

ERROR_LOG_FILE   The error log file full pathname.

ERROR_LOG_FILENAME_PREFIX   see *Configuration options*.

ERROR_LOG_SPLIT_MODE   see *Configuration options*.

FORCE_CLIENT_DATA_TIMEOUT   see *Configuration options*.

FORCE_CLIENT_HEADER_TIMEOUT   see *Configuration options*.

FORCE_SERVER_RESPONSE_TIMEOUT   see *Configuration options*.

FORCE_WAIT_FOR_CLIENT_TIMEOUT   see *Configuration options*.

FREE_SLOTS_KEEP_ALIVE_LIMIT   see *Configuration options*.

LINE_STACK_SIZE   see *Configuration options*.

KEYS_M (matrix tag)   A list of set of keys (for each key correspond a value in the tag VALUES_L, see below). Each key in the vector tag start with an *HTML* "<td>" tag. This is to be able to display the key/value in column.

LOG (boolean tag)   This is set to true if logging is active.

LOG_FILE   The log file full pathname.

LOG_FILENAME_PREFIX   see *Configuration options*.

LOG_FILE_DIRECTORY   see *Configuration options*.

LOG_MODE   The rotating log mode, this is either *NONE*, *DAILY*, *MONTHLY* or *EACH_RUN*.

LOGO   A string to be placed in an img *HTML* tag. This is the name of the *AWS* logo image.

MAX_CONCURRENT_DOWNLOAD   see *Configuration options*.

MAX_CONNECTION   see *Configuration options*.

PEER_NAME_V (vector tag)   A list of peer name. One for each connection. This is the name of the last peer connected to the slot.

PHASE_V (vector tag)   What is the slot currently doing, for example Server_Processing or Closed.

RECEIVE_TIMEOUT   see *Configuration options*.

REUSE_ADDRESS   see *Configuration options*.

SECURITY   A boolean set to True if this is a secure socket (HTTPS/SSL).

SECURITY_MODE   see *Configuration options*.

CIPHER_PRIORITIES   see *Configuration options*.

SEND_TIMEOUT   see *Configuration options*.

SERVER_HOST   see *Configuration options*.

SERVER_NAME   see *Configuration options*.

SERVER_PORT   see *Configuration options*.

SERVER_SOCK   Server socket ID.

SESSION   see *Configuration options*.

SESSION_CLEANUP_INTERVAL   Number of seconds between each run of the session cleanup task. This task will remove all session data that have been obsoleted.

SESSION_LIFETIME   Number of seconds to keep session information. After this period a session is obsoleted and will be removed at next cleanup.

SESSION_NAME   see *Configuration options*.

SESSIONS_TERMINATE_V (vector tag)   A list of time. Each item correspond to the time when the session will be obsoleted.

SESSIONS_TS_V (vector tag)   A list of time stamp. Each item correspond to a session last access time.

SESSIONS_V (vector tag)   A list of session ID.

SLOT_ACTIVITY_COUNTER_V (vector tag)   A list of natural. One for each connection. This is the total number of requests the slot has answered. This counter is never reseted.

SOCK_V (vector tag) A list of sockets ID. One for each connection.

STATUS_PAGE see *Configuration options*.

START_TIME A timestamp in YYYY-MM-DD HH:MM:SS format. When the server was started.

TRANSIENT_CLEANUP_INTERVAL see *Configuration options*.

TRANSIENT_LIFETIME see *Configuration options*.

UPLOAD_DIRECTORY see *Configuration options*.

UPLOAD_SIZE_LIMIT see *Configuration options*.

VALUES_M (matrix tag) A list of set of values (for each value correspond a key in the vector tag KEYS_L, see above). Each key in the vector tag start with an *HTML* "<td>" tag. This is to be able to display the key/value in column.

VERSION *AWS* version string.

WWW_ROOT see *Configuration options*.

There is also all *Templates_Parser* specific tags. This is not listed here please have a look at the *Templates_Parser* documentation distributed with *AWS*.

package AWS.Config is

   type Object is private;

   Default_Config : constant Object;

   --  For the external configuration to be loaded either Get_Current or
   --  Load_Config must be called explicitly.

   function Get_Current return Object;
   --  Returns a configuration record. This is the properties as read in files
   --  'aws.ini' and 'progname.ini'. This configuration object holds only the
```

```ada
   --  per-server options.

   procedure Load_Config;
   --  Load configuration and store it into an internal object. This can be
   --  called when only some server-wide configuration are to be set from
   --  .ini files for example.

   ------------------------
   -- Per Server options --
   ------------------------

   ------------
   -- Server --
   ------------

   function Server_Name (O : Object) return String with Inline;
   --  This is the name of the server as set by AWS.Server.Start

   function Protocol_Family (O : Object) return String with Inline;
   --  Server protocol family. Family_Inet for IPv4, Family_Inet6 for IPv6 and
   --  Family_Unspec for unspecified protocol family.

   function IPv6_Only (O : Object) return Boolean with Inline;
   --  IPv6 server accepts only IPv6 connections

   function Server_Host (O : Object) return String with Inline;
   --  This is the server host. Can be used if the computer has a more than
   --  one IP address. It is possible to have two servers at the same port
   --  on the same machine, both being binded on different IP addresses.

   function Server_Port (O : Object) return Natural with Inline;
   --  This is the server port as set by the HTTP object declaration

   function Hotplug_Port (O : Object) return Positive with Inline;
   --  This is the hotplug communication port needed to register and
   --  un-register an hotplug module.

   function Session (O : Object) return Boolean with Inline;
   --  Returns True if the server session is activated

   function Case_Sensitive_Parameters (O : Object) return Boolean with Inline;
   --  HTTP parameters are case sensitive

   function Session_Name (O : Object) return String with Inline;
   --  Name of the cookie session

   function Session_Private_Name (O : Object) return String with Inline;
   --  Name of the private cookie session

   function Server_Priority (O : Object) return System.Any_Priority
     with Inline;
   --  Returns the priority used by the HTTP and WebSockets servers

   function Server_Header (O : Object) return String with Inline;
   --  Returns the Server header value

   ----------------
   -- Connection --
```

```
   ----------------

   function Max_Connection (O : Object) return Positive with Inline;
   --   This is the max simultaneous connections as set by the HTTP object
   --   declaration.

   function Send_Buffer_Size (O : Object) return Natural with Inline;
   --   This is the socket buffer size used for sending data. Increasing this
   --   value will give better performances on slow or long distances
   --   connections.

   function TCP_No_Delay (O : Object) return Boolean with Inline;
   --   Returns wether the TCP_NODELAY option is set for this server

   function Free_Slots_Keep_Alive_Limit (O : Object) return Natural
     with Inline;
   --   The minimum number of free slots where keep-alive connections are still
   --   enabled. After this limit no more keep-alive connection will be
   --   accepted by the server. This parameter must be used for heavy-loaded
   --   servers to make sure the server will never run out of slots. This limit
   --   must be less than Max_Connection.

   function Keep_Alive_Force_Limit (O : Object) return Positive with Inline;
   --   Server could have more than Max_Connection keep-alive sockets. Keep
   --   alive sockets are waiting for client input in the internal server socket
   --   set. This parameter defines the maximum number of keep alive sockets
   --   processed by the server with standard timeouts. If number of keep-alive
   --   sockets becomes more than Keep_Alive_Force_Limit the server starts to
   --   use shorter timeouts. If this parameter is not defined in the
   --   configuration, the server uses Max_Connection * 2 as value.

   function Keep_Alive_Close_Limit (O : Object) return Positive with Inline;
   --   This parameter defines the limit of keep alive sockets in the internal
   --   server socket set. If the number of sockets in socket set became more
   --   than Keep_Alive_Close_Limit, most close to timeout socket would be
   --   closed. If this parameter is not defined in the configuration,
   --   the server uses Max_Connection * 4 as value.

   function Accept_Queue_Size (O : Object) return Positive with Inline;
   --   This is the size of the queue for the incoming requests. Higher this
   --   value will be and less "connection refused" will be reported to the
   --   client.

   function Line_Stack_Size (O : Object) return Positive with Inline;
   --   HTTP lines stack size

   function Reuse_Address (O : Object) return Boolean with Inline;
   --   Returns true if bind is allowed to reuse an address (not waiting for
   --   the delay between two bind to the same port).

   ----------
   -- Data --
   ----------

   function WWW_Root (O : Object) return String with Inline;
   --   This is the root directory name for the server. This variable is not
   --   used internally by AWS. It is supposed to be used by the callback
   --   procedures who want to retrieve physical objects (images, Web pages...).
```

```
   --  The default value is the current working directory. The returned
   --  directory ends with a directory separator.

   function Upload_Directory (O : Object) return String with Inline;
   --  This point to the directory where uploaded files will be stored. The
   --  directory returned will end with a directory separator.

   function Upload_Size_Limit (O : Object) return Positive with Inline;

   function Directory_Browser_Page (O : Object) return String with Inline;
   --  Filename for the directory browser template page

   function Max_POST_Parameters (O : Object) return Positive with Inline;
   --  Returns the maximum number of POST parameters handled. Past this limit
   --  the exception Too_Many_Parameters is raised.

   ----------
   -- Log --
   ----------

   function Log_Activated (O : Object) return Boolean with Inline;
   --  Whether the default log should be activated

   function Log_File_Directory (O : Object) return String with Inline;
   --  This point to the directory where log files will be written. The
   --  directory returned will end with a directory separator.

   function Log_Filename_Prefix (O : Object) return String with Inline;
   --  This is the prefix to use for the log filename

   function Log_Split_Mode (O : Object) return String with Inline;
   --  This is split mode for the log file. Possible values are : Each_Run,
   --  Daily, Monthly and None. Any other values will raise an exception.

   function Log_Size_Limit (O : Object) return Natural with Inline;

   generic
      with procedure Field_Id (Id : String);
   procedure Log_Extended_Fields_Generic_Iterate (O : Object);
   --  Calls procedure Field_Id for each extended http log field identifier

   function Log_Extended_Fields_Length (O : Object) return Natural with Inline;
   --  Returns the number of extended http log fileds identifiers.
   --  If returned value is zero then http log is not extended.

   function Error_Log_Activated (O : Object) return Boolean with Inline;
   --  Whether the error log should be activated

   function Error_Log_Filename_Prefix (O : Object) return String with Inline;
   --  This is the prefix to use for the log filename

   function Error_Log_Split_Mode (O : Object) return String with Inline;
   --  This is split mode for the log file. Possible values are : Each_Run,
   --  Daily, Monthly and None. Any other values will raise an exception.

   -----------
   -- Status --
   -----------
```

```ada
function Admin_Password (O : Object) return String with Inline;
--  The admin password

function Admin_Realm (O : Object) return String with Inline;
--  The admin password

function Admin_URI (O : Object) return String with Inline;
--  This is the name of the admin server page as set by AWS.Server.Start.
--  It is also known as the status page.

function Status_Page (O : Object) return String with Inline;
--  Filename for the status template page

function Up_Image (O : Object) return String with Inline;
--  Filename for the up arrow image used in the status page

function Down_Image (O : Object) return String with Inline;
--  Filename for the down arrow image used in the status page

function Logo_Image (O : Object) return String with Inline;
--  Filename for the AWS logo image used in the status page

--------------
-- Timeouts --
--------------

function Cleaner_Wait_For_Client_Timeout (O : Object) return Duration
  with Inline;
--  Number of seconds to timout on waiting for a client request.
--  This is a timeout for regular cleaning task.

function Cleaner_Client_Header_Timeout (O : Object) return Duration
  with Inline;
--  Number of seconds to timout on waiting for client header.
--  This is a timeout for regular cleaning task.

function Cleaner_Client_Data_Timeout (O : Object) return Duration
  with Inline;
--  Number of seconds to timout on waiting for client message body.
--  This is a timeout for regular cleaning task.

function Cleaner_Server_Response_Timeout (O : Object) return Duration
  with Inline;
--  Number of seconds to timout on waiting for client to accept answer.
--  This is a timeout for regular cleaning task.

function Force_Wait_For_Client_Timeout (O : Object) return Duration
  with Inline;
--  Number of seconds to timout on waiting for a client request.
--  This is a timeout for urgent request when resources are missing.

function Force_Client_Header_Timeout (O : Object) return Duration
  with Inline;
--  Number of seconds to timout on waiting for client header.
--  This is a timeout for urgent request when resources are missing.

function Force_Client_Data_Timeout (O : Object) return Duration with Inline;
```

```ada
   --  Number of seconds to timout on waiting for client message body.
   --  This is a timeout for urgent request when resources are missing.

   function Force_Server_Response_Timeout (O : Object) return Duration
     with Inline;
   --  Number of seconds to timout on waiting for client to accept answer.
   --  This is a timeout for urgent request when resources are missing.

   function Send_Timeout (O : Object) return Duration with Inline;
   --  Number of seconds to timeout when sending chunck of data

   function Receive_Timeout (O : Object) return Duration with Inline;
   --  Number of seconds to timeout when receiving chunck of data

   -------------
   -- Security --
   -------------

   function Check_URL_Validity (O : Object) return Boolean with Inline;
   --  Server have to check URI for validity. For example it checks that an
   --  URL does not reference a resource above the Web root.

   function Security (O : Object) return Boolean with Inline;
   --  Is the server working through th SSL

   function Certificate (O : Object) return String with Inline;
   --  Returns the certificate to be used with the secure server. Returns the
   --  empty string if the server is not a secure one.

   function Key (O : Object) return String with Inline;
   --  Returns the key to be used with the secure server. Returns the
   --  empty string if the server is not a secure one.

   function Security_Mode (O : Object) return String with Inline;
   --  Returns the security mode to be used with the secure server. Returns the
   --  empty string if the server is not a secure one.

   function Cipher_Priorities (O : Object) return String with Inline;
   --  Returns the cipher priorities for the security communication

   function TLS_Ticket_Support (O : Object) return Boolean with Inline;
   --  Is security communication side has support stateless TLS session
   --  resumption. See RFC 5077.

   function Exchange_Certificate (O : Object) return Boolean with Inline;
   --  Returns True if the client is requested to send its certificate to the
   --  server.

   function Certificate_Required (O : Object) return Boolean with Inline;
   --  Returns True if the server must abort the connection if the
   --  client did not provide trusted certificate. If this option is set
   --  the Exchange_Certificate must also be set.

   function Trusted_CA (O : Object) return String with Inline;
   --  Returns the filename containing a list of trusted CA, this is to be used
   --  with the Exchange_Certificate option. The filename is on bundle of CAs
   --  that can be trusted. A client certificate signed with one of those CA
   --  will be accetped by the server.
```

```ada
function CRL_File (O : Object) return String with Inline;
--  Returns the filename containing the Certificate Revocation List. This
--  list is used by the server to check for revoked certificate.

function SSL_Session_Cache_Size (O : Object) return Natural with Inline;
--  Returns SSL session cashe size

--------------------------
-- Per Process options --
--------------------------

function Session_Cleanup_Interval return Duration with Inline;
--  Number of seconds between each run of the cleaner task to remove
--  obsolete session data.

function Session_Lifetime return Duration with Inline;
--  Number of seconds to keep a session if not used. After this period the
--  session data is obsoleted and will be removed during next cleanup.

function Session_Id_Length return Positive with Inline;
--  Returns the length (number of characters) of the session id

function Session_Cleaner_Priority return System.Any_Priority with Inline;
--  Returns the priority used by the session cleaner task

function Service_Priority return System.Any_Priority with Inline;
--  Returns the priority used by the others services (SMTP server, Jabber
--  server, Push server...).

function Config_Directory return String with Inline;
--  Directory where AWS parameter files are located

function Transient_Cleanup_Interval return Duration with Inline;
--  Number of seconds between each run of the cleaner task to remove
--  transient pages.

function Transient_Lifetime return Duration with Inline;
--  Number of seconds to keep a transient page. After this period the
--  transient page is obsoleted and will be removed during next cleanup.

function Max_Concurrent_Download return Positive with Inline;
--  Number of maximum concurrent download supported by the download manager
--  service.

function MIME_Types return String with Inline;
--  Returns the file name of the MIME types to use

function Input_Line_Size_Limit return Positive with Inline;
--  Limit of the HTTP protocol text lines length

function Context_Lifetime return Duration with Inline;
--  Number of seconds to keep a context if not used. After this period the
--  context data is obsoleted and will be removed during next cleanup.

function Max_WebSocket_Handler return Positive with Inline;
--  This is the max simultaneous connections handling WebSocket's messages
```

```ada
   function WebSocket_Message_Queue_Size return Positive with Inline;
   --  This is the size of the queue containing incoming messages

   function WebSocket_Send_Message_Queue_Size return Positive with Inline;
   --  This is the size of the queue containing messages to send

   function Max_WebSocket return Positive with Inline;
   --  The maximum number of simultaneous WebSocket opened. Note that that
   --  there could be more WebSocket registered when counting the closing
   --  WebSockets.

   function WebSocket_Timeout return Duration with Inline;
   --  Returns the WebSocket activity timeout. After this number of seconds
   --  without any activity the WebSocket can be closed when needed.

   function Is_WebSocket_Origin_Set return Boolean with Inline;
   --  Returns True if the Origin has been set

   function WebSocket_Origin return GNAT.Regexp.Regexp;
   --  This is regular expression to restrict WebSocket to a specific origin

   function WebSocket_Origin return String;
   --  This is the string regular expression to restrict WebSocket to a
   --  specific origin.

   function WebSocket_Priority return System.Any_Priority;
   --  Set the priority used by the WebSocket service

   function User_Agent return String with Inline;
   --  Returns the User_Agent header value

private
   --  implementation removed
end AWS.Config;

--  This package can be used to Set any AWS parameters

package AWS.Config.Set is

   -----------------------
   -- Per Server Options --
   -----------------------

   -----------
   -- Server --
   -----------

   procedure Server_Name (O : in out Object; Value : String);
   --  This is the name of the server as set by AWS.Server.Start

   procedure Protocol_Family (O : in out Object; Value : String);
   --  Set the server protocol family. Family_Inet for IPv4, Family_Inet6 for
   --  IPv6 and Family_Unspec for unspecified protocol family.

   procedure IPv6_Only (O : in out Object; Value : Boolean);
   --  Set the mode when IPv6 server allows connect only IPv6 clients

   procedure Server_Host (O : in out Object; Value : String);
   --  This is the server host as set by the HTTP object declaration

   procedure Server_Port (O : in out Object; Value : Natural);
   --  This is the server port as set by the HTTP object declaration
```

```ada
   procedure Hotplug_Port (O : in out Object; Value : Positive);
   --  This is the hotplug communication port needed to register and
   --  un-register an hotplug module.

   procedure Session (O : in out Object; Value : Boolean);
   --  Enable session handling is Value is True

   procedure Case_Sensitive_Parameters (O : in out Object; Value : Boolean);
   --  Parameters are handled with the case if Value is True

   procedure Line_Stack_Size (O : in out Object; Value : Positive);
   --  HTTP lines stack size

   procedure Reuse_Address (O : in out Object; Value : Boolean);
   --  Set the reuse address policy allowing a bind without a dealy to the same
   --  address and port.

   procedure Session_Name (O : in out Object; Value : String);
   --  Name of the cookie session

   procedure Server_Priority (O : in out Object; Value : System.Any_Priority);
   --  Set the priority used by the HTTP and WebSockets servers

   procedure Server_Header (O : in out Object; Value : String);
   --  Set the server header (value used by the Server: request header)

   ----------------
   -- Connection --
   ----------------

   procedure Max_Connection (O : in out Object; Value : Positive);
   --  This is the max simultaneous connections as set by the HTTP object
   --  declaration.

   procedure Send_Buffer_Size (O : in out Object; Value : Positive);
   --  This is the socket buffer size used for sending data. Increasing this
   --  value will give better performances on slow or long distances
   --  connections.

   procedure TCP_No_Delay (O : in out Object; Value : Boolean);
   --  Set the TCP_NODELAY option for this server

   procedure Free_Slots_Keep_Alive_Limit
     (O : in out Object; Value : Natural);
   --  The minimum number of free slots where keep-alive connections are still
   --  enabled. After this limit no more keep-alive connection will be
   --  accepted by the server. This parameter must be used for heavy-loaded
   --  servers to make sure the server will never run out of slots. This limit
   --  must be less than Max_Connection.

   procedure Keep_Alive_Force_Limit (O : in out Object; Value : Natural);
   --  Define maximum number of keep alive sockets where server process it with
   --  normal timeouts. If number of keep-alive sockets become more than
   --  Keep_Alive_Force_Limit, server start to use shorter force timeouts.
   --  If this parameter not defined in configuration or defined as 0 value
   --  server use calculated value Max_Connection * 2.
```

```ada
   procedure Accept_Queue_Size (O : in out Object; Value : Positive);
   --  This is the size of the queue for the incoming requests. Higher this
   --  value will be and less "connection refused" will be reported to the
   --  client.

   ----------
   -- Data --
   ----------

   procedure WWW_Root (O : in out Object; Value : String);
   --  This is the root directory name for the server. This variable is not
   --  used internally by AWS. It is supposed to be used by the callback
   --  procedures who want to retrieve physical objects (images, Web
   --  pages...). The default value is the current working directory.

   procedure Upload_Directory (O : in out Object; Value : String);
   --  This point to the directory where uploaded files will be stored. The
   --  directory returned will end with a directory separator.

   procedure Upload_Size_Limit (O : in out Object; Value : Positive);
   --  Set the maximum size accepted for uploaded files

   procedure Directory_Browser_Page (O : in out Object; Value : String);
   --  Filename for the directory browser template page

   procedure Max_POST_Parameters (O : in out Object; Value : Positive);
   --  Set the maximum number of POST parameters handled. Past this limit
   --  the exception Too_Many_Parameters is raised.

   ---------
   -- Log --
   ---------

   procedure Log_Activated (O : in out Object; Value : Boolean);
   --  Whether the default log should be activated

   procedure Log_File_Directory (O : in out Object; Value : String);
   --  This point to the directory where log files will be written. The
   --  directory returned will end with a directory separator.

   procedure Log_Filename_Prefix (O : in out Object; Value : String);
   --  This is the prefix to use for the log filename

   procedure Log_Size_Limit (O : in out Object; Value : Natural);
   --  If Log_Size_Limit is more than zero and size of log file
   --  become more than Log_Size_Limit, log file is be split.

   procedure Log_Split_Mode (O : in out Object; Value : String);
   --  This is split mode for the log file. Possible values are : Each_Run,
   --  Daily, Monthly and None. Any other values will raise an exception.

   procedure Log_Extended_Fields (O : in out Object; Value : String);
   --  Comma separated list of the extended log field names. If this parameter
   --  is empty, the HTTP log would have fixed apache compartible format:
   --
   --  127.0.0.1 - - [25/Apr/1998:15:37:29 +0200] "GET / HTTP/1.0" 200 1363
   --
   --  If the extended fields list is not empty, the log file format would have
```

```
--   user defined fields set:
--
--   #Version: 1.0
--   #Date: 2006-01-09 00:00:01
--   #Fields: date time cs-method cs-uri cs-version sc-status sc-bytes
--   2006-01-09 00:34:23 GET /foo/bar.html HTTP/1.1 200 30
--
--   Fields in the list could be:
--
--   date         Date at which transaction completed
--   time         Time at which transaction completed
--   c-ip         Client side connected IP address
--   c-port       Client side connected port
--   s-ip         Server side connected IP address
--   s-port       Server side connected port
--   cs-method    HTTP request method
--   cs-username  Client authentication username
--   cs-version   Client supported HTTP version
--   cs-uri       Request URI
--   cs-uri-stem  Stem portion alone of URI (omitting query)
--   cs-uri-query Query portion alone of URI
--   sc-status    Responce status code
--   sc-bytes     Length of response message body
--   cs(<header>) Any header field name sent from client to server
--   sc(<header>) Any header field name sent from server to client
--   x-<appfield> Any application defined field name

procedure Error_Log_Activated (O : in out Object; Value : Boolean);
--   Whether the error log should be activated

procedure Error_Log_Filename_Prefix (O : in out Object; Value : String);
--   This is the prefix to use for the log filename

procedure Error_Log_Split_Mode (O : in out Object; Value : String);
--   This is split mode for the log file. Possible values are : Each_Run,
--   Daily, Monthly and None. Any other values will raise an exception.

-----------
-- Status --
-----------

procedure Admin_Password (O : in out Object; Value : String);
--   This is the password for the admin server page as set by
--   AWS.Server.Start. The password must be created with the aws_password
--   tool.

procedure Admin_URI (O : in out Object; Value : String);
--   This is the name of the admin server page as set by AWS.Server.Start

procedure Status_Page (O : in out Object; Value : String);
--   Filename for the status template page

procedure Up_Image (O : in out Object; Value : String);
--   Filename for the up arrow image used in the status page

procedure Down_Image (O : in out Object; Value : String);
--   Filename for the down arrow image used in the status page
```

```ada
   procedure Logo_Image (O : in out Object; Value : String);
   -- Filename for the AWS logo image used in the status page

   -------------
   -- Timeouts --
   -------------

   procedure Cleaner_Wait_For_Client_Timeout
     (O     : in out Object;
      Value : Duration);
   -- Number of seconds to timout on waiting for a client request.
   -- This is a timeout for regular cleaning task.

   procedure Cleaner_Client_Header_Timeout
     (O     : in out Object;
      Value : Duration);
   -- Number of seconds to timout on waiting for client header.
   -- This is a timeout for regular cleaning task.

   procedure Cleaner_Client_Data_Timeout
     (O     : in out Object;
      Value : Duration);
   -- Number of seconds to timout on waiting for client message body.
   -- This is a timeout for regular cleaning task.

   procedure Cleaner_Server_Response_Timeout
     (O     : in out Object;
      Value : Duration);
   -- Number of seconds to timout on waiting for client to accept answer.
   -- This is a timeout for regular cleaning task.

   procedure Force_Wait_For_Client_Timeout
     (O     : in out Object;
      Value : Duration);
   -- Number of seconds to timout on waiting for a client request.
   -- This is a timeout for urgent request when resources are missing.

   procedure Force_Client_Header_Timeout
     (O     : in out Object;
      Value : Duration);
   -- Number of seconds to timout on waiting for client header.
   -- This is a timeout for urgent request when resources are missing.

   procedure Force_Client_Data_Timeout
     (O     : in out Object;
      Value : Duration);
   -- Number of seconds to timout on waiting for client message body.
   -- This is a timeout for urgent request when resources are missing.

   procedure Force_Server_Response_Timeout
     (O     : in out Object;
      Value : Duration);
   -- Number of seconds to timout on waiting for client to accept answer.
   -- This is a timeout for urgent request when resources are missing.

   procedure Send_Timeout (O  : in out Object; Value : Duration);
   -- Number of seconds to timeout when sending chunck of data
```

```ada
   procedure Receive_Timeout (O : in out Object; Value : Duration);
   --  Number of seconds to timeout when receiving chunck of data

   -------------
   -- Security --
   -------------

   procedure Check_URL_Validity (O : in out Object; Value : Boolean);
   --  Set the check URL validity flag. If True an URL that reference a
   --  resource above the Web root will be rejected.

   procedure Security (O : in out Object; Value : Boolean);
   --  Enable security (HTTPS/SSL) if Value is True

   procedure Certificate (O : in out Object; Filename : String);
   --  Set the certificate filename in PEM format to be used with the secure
   --  server.

   procedure Key (O : in out Object; Filename : String);
   --  Set the key to be used with the secure server

   procedure Security_Mode (O : in out Object; Mode : String);
   --  Set the security mode to be used with the secure server. Only values
   --  from AWS.Net.SSL.Method can be used.

   procedure Cipher_Priorities (O : in out Object; Value : String);
   --  Sets priorities for the cipher suites supported by SSL implementation.
   --  GNUTLS and OpenSSL implementations has different sintax for this
   --  parameter.

   procedure TLS_Ticket_Support (O : in out Object; Value : Boolean);
   --  Set to True for security communication side support stateless TLS
   --  session resumption. See RFC 5077.

   procedure Exchange_Certificate (O : in out Object; Value : Boolean);
   --  Set to True to request the client to send its certificate to the server

   procedure Certificate_Required (O : in out Object; Value : Boolean);
   --  Returns True if the server must abort the connection if the
   --  client did not provide a certificate. If this option is set
   --  the Exchange_Certificate must also be set.

   procedure Trusted_CA (O : in out Object; Filename : String);
   --  Returns the filename containing a list of trusted CA, this is to be used
   --  with the Exchange_Certificate option. The filename is on bundle of CAs
   --  that can be trusted. A client certificate signed with one of those CA
   --  will be accetped by the server.

   procedure CRL_File (O : in out Object; Filename : String);
   --  Returns the filename containing the Certificate Revocation List. This
   --  list is used by the server to check for revoked certificate.

   procedure SSL_Session_Cache_Size (O : in out Object; Value : Natural);

   ------------------------
   -- Per Process Options --
   ------------------------
```

```ada
procedure Session_Cleanup_Interval (Value : Duration);
-- Number of seconds between each run of the cleaner task to remove
-- obsolete session data.

procedure Session_Lifetime (Value : Duration);
-- Number of seconds to keep a session if not used. After this period the
-- session data is obsoleted and will be removed during next cleanup.

procedure Session_Id_Length (Value : Positive);
-- Returns the length (number of characters) of the session id

procedure Session_Cleaner_Priority (Value : System.Any_Priority);
-- Set the priority used by the session cleaner task

procedure Service_Priority (Value : System.Any_Priority);
-- Set the priority used by the others services (SMTP server, Jabber
-- server, Push server...).

procedure Config_Directory (Value : String);
-- Directory where AWS parameter files are located

procedure Transient_Cleanup_Interval (Value : Duration);
-- Number of seconds between each run of the cleaner task to remove
-- transient pages.

procedure Transient_Lifetime (Value : Duration);
-- Number of seconds to keep a transient page. After this period the
-- transient page is obsoleted and will be removed during next cleanup.

procedure Context_Lifetime (Value : Duration);
-- Number of seconds to keep a context if not used. After this period the
-- context data is obsoleted and will be removed during next cleanup.

procedure Max_Concurrent_Download (Value : Positive);
-- Control the maximum number of parallel downloads accepted by the
-- download manager.

procedure Max_WebSocket (Value : Positive);
-- The maximum number of simultaneous WebSocket opened. Note that that
-- there could be more WebSocket registered when counting the closing
-- WebSockets.

procedure Max_WebSocket_Handler (Value : Positive);
-- This is the max simultaneous connections handling WebSocket's messages

procedure MIME_Types (Value : String);
-- The name of the file containing the MIME types associations

procedure WebSocket_Message_Queue_Size (Value : Positive);
-- This is the size of the queue containing incoming messages

procedure WebSocket_Send_Message_Queue_Size (Value : Positive);
-- This is the size of the queue containing messages to send

procedure WebSocket_Origin (Value : String);
-- This is regular expression to restrict WebSocket to a specific origin

procedure WebSocket_Priority (Value : System.Any_Priority);
```

```ada
   --  Set the priority used by the WebSocket service

   procedure WebSocket_Timeout (Value : Duration);
   --  Returns the WebSocket activity timeout. After this number of seconds
   --  without any activity the WebSocket can be closed when needed.

   procedure Input_Line_Size_Limit (Value : Positive);
   --  Maximum length of an HTTP parameter

   procedure User_Agent (Value : String);
   --  Set the user agent for client request heaser

   procedure Parameter
     (Config        : in out Object;
      Name          : String;
      Value         : String;
      Error_Context : String := "");
   --  Set one of the AWS HTTP per server parameters. Raises Constraint_Error
   --  in case of wrong parameter name or wrong parameter value.
   --  Error_Context may contain additional information about the parameter.
   --  This  message will be added to the Constraint_Error exception.
   --  One way to use Error_Context is to set it with information about
   --  where this parameter come form.

   procedure Parameter
     (Name          : String;
      Value         : String;
      Error_Context : String := "");
   --  Set one of the AWS HTTP per process parameters. See description above

end AWS.Config.Set;

--  Activate server's activity logging. Split indicate the way the log file
--  should be created. If Size_Limit more than zero and size of log file
--  become more than Size_Limit, log file would be splitted. Filename_Prefix
--  is the log filename prefix. If it is not specified the default prefix is
--  the program name. Set Auto_Flush to True if you want every write to the
--  log to be flushed (not buffered). Auto_Flush should be set to True only
--  for logs with few entries per second as the flush has a performance
--  penalty.

procedure Start
  (Log    : in out Object;
   Writer : Callback;
   Name   : String);
--  Activate server's activity logging and send all log data to Callback.
--  When the logging object is started with a Callback no splitting or size
--  limits are imposed on the logging data. This will all have to be handled
--  in the Callback.
--  When a log is started with a Callback, all log data is passed verbatim
--  to the Callback.
--  The Name String is returned when the Filename function is called. This
--  serves no other function than to label the Callback procedure.

procedure Register_Field (Log : in out Object; Id : String);
--  Register field to be written into extended log format

procedure Set_Field
  (Log : Object; Data : in out Fields_Table; Id, Value : String);
--  Set field value into the extended log record. Data could be used only
--  in one task and with one log file. Different tasks could write own Data
```

```ada
--  using the Write routine with Fields_Table parameter type.

procedure Set_Header_Fields
  (Log    : Object;
   Data   : in out Fields_Table;
   Prefix : String;
   Header : AWS.Headers.List);
--  Set header fields into extended log record.
--  Name of the header fields would be <Prefix>(<Header_Name>).
--  Prefix should be "cs" - Client to Server or "sc" - Server to Client.

procedure Write (Log : in out Object; Data : in out Fields_Table);
--  Write extended format record to log file and prepare record for the next
--  data. It is not allowed to use same Fields_Table with different extended
--  logs.

      User_04,
      User_05);

   --
   --  The following three methods are the one to override or redefine. In fact
   --  the default Send implementation should be ok for most usages.
   --

   function Create
     (Socket  : Socket_Access;
      Request : AWS.Status.Data) return Object'Class
   with Pre => Socket /= null;
   --  Create a new instance of the WebSocket, this is used by AWS internal
   --  server to create a default WebSocket if no other constructor are
   --  provided. It is also needed when deriving from WebSocket.
   --
   --  This function must be registered via AWS.Net.WebSocket.Registry.Register

   procedure On_Message (Socket : in out Object; Message : String) is null;
   --  Default implementation does nothing, it needs to be overriden by the
   --  end-user. This is the callback that will get activated for every server
   --  incoming data. It is also important to keep in mind that the thread
   --  handling this WebSocket won't be released until the procedure returns.
   --  So the code inside this routine should be small and most importantly not
   --  wait for an event to occur otherwise other requests won't be served.

   procedure On_Message (Socket : in out Object; Message : Unbounded_String);
   --  Same a above but takes an Unbounded_String. This is supposed to be
   --  overriden when handling large messages otherwise a stack-overflow could
   --  be raised. The default implementation of this procedure to to call the
   --  On_Message above with a string.
   --
   --  So either this version is overriden to handle the incoming messages or
   --  the one above if the messages are known to be small.

   procedure On_Open (Socket : in out Object; Message : String) is null;
   --  As above but activated when a WebSocket is opened

   procedure On_Close (Socket : in out Object; Message : String) is null;
   --  As above but activated when a WebSocket is closed

   procedure On_Error (Socket : in out Object; Message : String) is null;
   --  As above but activated when a WebSocket error is detected
```

```ada
procedure Send
  (Socket    : in out Object;
   Message   : String;
   Is_Binary : Boolean := False);
-- This default implementation just send a message to the client. The
-- message is sent in a single chunk (not fragmented).

procedure Send
  (Socket    : in out Object;
   Message   : Unbounded_String;
   Is_Binary : Boolean := False);
-- Same as above but can be used for large messages. The message is
-- possibly sent fragmented.

procedure Send
  (Socket    : in out Object;
   Message   : Stream_Element_Array;
   Is_Binary : Boolean := True);
-- As above but default is a binary message

procedure Close
  (Socket  : in out Object;
   Message : String;
   Error   : Error_Type := Normal_Closure);
-- Send a close frame to the WebSocket

--
-- Client side
--

procedure Connect
  (Socket : in out Object'Class;
   URI    : String);
-- Connect to a remote server using websockets.
-- Socket can then be used to Send messages to the server. It will
-- also receive data from the server, via the On_Message, when you call
-- Poll

function Poll
  (Socket  : in out Object'Class;
   Timeout : Duration) return Boolean;
-- Wait for up to Timeout seconds for some message.
--
-- In the websockets protocol, a message can be split (by the server)
-- onto several frames, so that for instance the server doesn't have to
-- store the whole message in its memory.
-- The size of those frames, however, is not limited, and they will
-- therefore possibly be split into several chunks by the transport
-- layer.
--
-- These function waits until it either receives a close or an error, or
-- the beginning of a message frame. In the latter case, the function
-- will then block until it has receives all chunks of that frame, which
-- might take longer than Timeout.
--
-- The function will return early if it doesn't receive the beginning
-- of a frame within Timeout seconds.
```

```
   --
   --  When a full frame has been received, it will be sent to the
   --  Socket.On_Message primitive operation. Remember this might not be the
   --  whole message however, and you should check Socket.End_Of_Message to
   --  check.

     return Data
   with Post => not Is_Empty (Moved'Result)
               and then Status_Code (Moved'Result) = Messages.S301;
   --  This send back a moved message (Messages.S301) with the specified
   --  message body and content type.
   --  This is a permanent redirection, and the client browser is encouraged
   --  to update links so that the next query for the URL goes directly to
   --  the new location.

   ------------------------
```

```ada
   -- Other Constructors --
   -----------------------

   function Acknowledge
     (Status_Code  : Messages.Status_Code;
      Message_Body : String := "";
      Content_Type : String := MIME.Text_HTML) return Data
   with Post =>
        not Is_Empty (Acknowledge'Result)
        and then Response.Status_Code (Acknowledge'Result) = Status_Code
        and then (if Message_Body = ""
                  then Mode (Acknowledge'Result) = Header);
   --  Returns a message to the Web browser. This routine must be used to
   --  send back an error message to the Web browser. For example if a
   --  requested resource cannot be served a message with status code S404
   --  must be sent.

   function Authenticate
     (Realm   : String;
      Mode    : Authentication_Mode := Basic;
      Stale   : Boolean             := False;
      Message : String              := Default_Authenticate_Message)
      return Data
   with Post => not Is_Empty (Authenticate'Result)
                and then Status_Code (Authenticate'Result) = Messages.S401;
   --  Returns an authentication message (Messages.S401), the Web browser
   --  will then ask for an authentication. Realm string will be displayed
   --  by the Web Browser in the authentication dialog box.

   function Socket_Taken return Data with
     Post => not Is_Empty (Socket_Taken'Result)
             and then Mode (Socket_Taken'Result) = Socket_Taken;
   --  Must be used to say that the connection socket has been taken by user
   --  inside of user callback. No operations should be performed on this
   --  socket, and associated slot should be released for further operations.

   function Empty return Data with
     Post => Status_Code (Empty'Result) = Messages.S204
             and then Mode (Empty'Result) = No_Data;
   --  Returns an empty message (Data_Mode = No_Data and Status_Code is 204).
   --  It is used to say that user's handlers were not able to do something
   --  with the request. This is used by the callback's chain in the
   --  dispatchers and should not be used by users.

   --
   --  API to retrieve response data
   --

   -----------
   -- Header --
   -----------

   function Header (D : Data; Name : String; N : Positive) return String
     with Inline;
   --  Return the N-th value for header Name

   function Header (D : Data; Name : String) return String with Inline;
   --  Return all values as a comma-separated string for header Name.
```

```ada
--  See [RFC 2616 - 4.2] last paragraph.

function Header (D : Data) return AWS.Headers.List;

function Has_Header (D : Data; Name : String) return Boolean with Inline;
--  Returns True if D headers contains Name

procedure Send_Header (Socket : Net.Socket_Type'Class; D : Data)
  with Inline;
--  Send all header lines to the socket

function Status_Code (D : Data) return Messages.Status_Code with Inline;
--  Returns the status code

function Content_Length (D : Data) return Content_Length_Type with Inline;
--  Returns the content length (i.e. the message body length). A value of 0
--  indicate that there is no message body.

function Content_Type (D : Data) return String with Inline;
--  Returns the MIME type for the message body

function Cache_Control (D : Data) return Messages.Cache_Option with Inline;
--  Returns the cache control specified for the response

function Cache_Control (D : Data) return Messages.Cache_Data;
--  As above but returns a structured record of type "Cache_Data (Request)"
--  representing the cache options.

function Expires (D : Data) return Calendar.Time with Inline;
--  Returns the Expires date as a time value

function Location (D : Data) return String with Inline;
--  Returns the location for the new page in the case of a moved
--  message. See Moved constructor above.

----------
-- Data --
----------

function Mode (D : Data) return Data_Mode with Inline;
--  Returns the data mode, either Header, Message or File

function Is_Empty (D : Data) return Boolean with Inline;
--  Returns True if D.Mode is No_Data

function Message_Body (D : Data) return String with Inline;
--  Returns the message body content as a string.
--  Message_Body routines could not be used with user defined streams
--  (see. Stream routine in this package). Constraint_Error would be raised
--  on try to get data by the Message_Body from the user defined streams.
--  For get data from user defined streams routine Create_Resource should
--  be used.

function Message_Body (D : Data) return Unbounded_String;
--  Returns message body content as an unbounded_string

function Message_Body (D : Data) return Stream_Element_Array;
--  Returns message body as a binary content
```

```ada
   procedure Message_Body
     (D    : Data;
      File : out AWS.Resources.File_Type);
   --  Returns the message body as a stream

   function Filename (D : Data) return String with Inline;
   --  Returns the filename which should be sent back or the filename which
   --  was containing the response for a server response.

   -------------------
   -- Authentication --
   -------------------

   function Realm (D : Data) return String with Inline;
   --  Returns the Realm for the current authentication request

   function Authentication (D : Data) return Authentication_Mode with Inline;
   --  Returns the authentication mode requested by server

   function Authentication_Stale (D : Data) return Boolean with Inline;
   --  Returns the stale parameter for authentication

   --------------
   -- Resources --
   --------------

   procedure Create_Resource
     (D    : in out Data;
      File : out AWS.Resources.File_Type;
      GZip : Boolean)
   with Inline;
   --  Creates the resource object (either a file or in-memory object) for
   --  the data to be sent to the client. The resource should be closed after
   --  use.
   --  GZip is true when the http client support GZip decoding,
   --  if file or embedded resource is in the GZip format this routine would
   --  define Content-Encoding header field value.

   function Close_Resource (D : Data) return Boolean;
   --  Returns True if the resource stream must be close

   function Keep_Alive (D : Data) return Boolean with Inline;
   --  Returns True if the user want to keep connection alive

   ---------------
   -- WebSockets --
   ---------------

   function WebSocket return Data with
     Post => not Is_Empty (WebSocket'Result)
             and then Status_Code (WebSocket'Result) = Messages.S101
             and then Mode (WebSocket'Result) = WebSocket;
   --  WebSocket handshake from initial WebSocket connection
private
   --  implementation removed
end AWS.Response;
```

package AWS.Server is
```

```ada
type HTTP is limited private;
-- A Web server

--------------------------
-- Server initialization --
--------------------------

-- Note that starting a sercure server if AWS has not been configured to
-- support HTTPS will raise Program_Error.

procedure Start
  (Web_Server : in out HTTP;
   Callback   : Response.Callback;
   Config     : AWS.Config.Object);
-- Start server using a full configuration object. With this routine it is
-- possible to control all features of the server. A simplified version of
-- Start is also provided below with the most common options.

procedure Start
  (Web_Server : in out HTTP;
   Dispatcher : Dispatchers.Handler'Class;
   Config     : AWS.Config.Object);
-- Idem, but using the dispatcher tagged type instead of callback. See
-- AWS.Services.Dispatchers and AWS.Dispatchers hierarchies for built-in
-- services and interface to build your own dispatcher models.
-- Note that a copy of the Dispatcher is kept into Web_Server. Any
-- changes done to the Dispatcher object will not be part of the Web
-- server dispatcher.

procedure Get_Message_Body;
-- If size of message body is bigger than Upload_Size_Limit configuration
-- parameter, server do not receive message body before calling user's
-- callback routine. If user decide to get the message body he should call
-- this routine.

procedure Start
  (Web_Server               : in out HTTP;
   Name                     : String;
   Callback                 : Response.Callback;
   Max_Connection           : Positive  := Default.Max_Connection;
   Admin_URI                : String    := Default.Admin_URI;
   Port                     : Natural   := Default.Server_Port;
   Security                 : Boolean   := False;
   Session                  : Boolean   := False;
   Case_Sensitive_Parameters : Boolean  := True;
   Upload_Directory         : String    := Default.Upload_Directory;
   Line_Stack_Size          : Positive  := Default.Line_Stack_Size);
-- Start the Web server. Max_Connection is the number of simultaneous
-- connections the server's will handle (the number of slots in AWS).
-- Name is just a string used to identify the server. This is used
-- for example in the administrative page. Admin_URI must be set to enable
-- the administrative status page. Callback is the procedure to call for
-- each resource requested. Port is the Web server port. If Security is
-- set to True the server will use an HTTPS/SSL connection. If Session is
-- set to True the server will be able to get a status for each client
-- connected. A session Id is used for that, on the client side it is a
-- cookie. Case_Sensitive_Parameters if set to False it means that the
-- parameters name will be handled without case sensitivity. Upload
```

```
--  directory point to a directory where uploaded files will be stored.

----------------------
-- Server termination --
----------------------

procedure Shutdown (Web_Server : in out HTTP);
--  Stop the server and release all associated memory. This routine can
--  take some time to terminate because it waits for all tasks to terminate
--  properly before releasing the memory. The log facilities will be
--  automatically stopped by calling Stop_Log below.

type Termination is (No_Server, Q_Key_Pressed, Forever);

procedure Wait (Mode : Termination := No_Server);
--  The purpose of this procedure is to control the main procedure
--  termination. This procedure will return only when no server are running
--  (No_Server mode) or the 'q' key has been pressed. If mode is set to
--  Forever, Wait will never return and the process will have to be killed.

------------------------
-- Server configuration --
------------------------

function Config (Web_Server : HTTP) return AWS.Config.Object;
--  Returns configuration object for Web_Server

procedure Set_Unexpected_Exception_Handler
  (Web_Server : in out HTTP;
   Handler    : Exceptions.Unexpected_Exception_Handler);
--  Set the unexpected exception handler. It is called whenever an
--  unrecoverable error has been detected. The default handler just display
--  (on standard output) an error message with the location of the
--  error. By changing this handler it is possible to log or display full
--  symbolic stack backtrace if needed.

procedure Set
  (Web_Server : in out HTTP;
   Dispatcher : Dispatchers.Handler'Class);
--  Dynamically associate a new dispatcher object to the server. With the
--  feature it is possible to change server behavior at runtime. The
--  complete set of callback procedures will be changed when calling this
--  routine. Note that any change in a dispatcher associated with a server
--  using Register or Unregister must be reset into the server using this
--  routine.

procedure Set_Security
  (Web_Server           : in out HTTP;
   Certificate_Filename : String;
   Security_Mode        : Net.SSL.Method := Net.SSL.TLS_Server;
   Key_Filename         : String         := "");
--  Set security option for AWS. Certificate_Filename is the name of a file
--  containing a certificate. Key_Filename is the name of the file
--  containing the key, if the empty string the key will be taken from the
--  certificate filename. This must be called before starting the secure
--  server otherwise the default security options or options set in the
--  config files will be used. After that the call will have no effect.
```

```ada
procedure Set_SSL_Config
  (Web_Server : in out HTTP; SSL_Config : Net.SSL.Config);
-- Set the SSL configuration for this server

function SSL_Config
  (Web_Server : in out HTTP) return not null access Net.SSL.Config;
-- Returns the access to SSL config of the server. Allow to change SSL
-- config on the already created server.

procedure Set_Socket_Constructor
  (Web_Server         : in out HTTP;
   Socket_Constructor : Net.Socket_Constructor);
-- Set the socket constructor routine to use when creating new sockets on
-- the server. By calling this routine it is possible to replace the
-- default AWS communication layer used. The default constructor is
-- AWS.Net.Socket. Note that this routine must be called before starting
-- the server. It is also important to note that sockets returned by the
-- constructor must have the cache properly initialized. See AWS.Net.Cache
-- for more information.

type HTTP_Access is access all HTTP;

function Get_Current return not null access HTTP;
-- Get current server. This can be used in a callback procedure to
-- retrieve the running HTTP server. It is needed when a callback
-- procedure is shared by multiple servers.

function Get_Status return Status.Data;
-- Returns the current status data. This is useful to get the full status
-- in a templates engine callback procedure for example.

function Session_Name return String;
-- Returns the current session cookie name

function Session_Private_Name return String;
-- Returns the current private session cookie name

---------------
-- Other API --
---------------

procedure Give_Back_Socket
  (Web_Server : in out HTTP; Socket : Net.Socket_Type'Class);
-- Give the socket back to the server. Socket must have been taken from
-- the server using the Response.Socket_Taken routine in a callback.

procedure Give_Back_Socket
  (Web_Server : in out HTTP;
   Socket     : not null access Net.Socket_Type'Class);
-- Idem.
-- Use Socket_Access to avoid memory reallocation for already allocated
-- sockets.

procedure Set_Field (Id, Value : String);
-- Set the extended log field value for the server the controlling the
-- current task.

procedure Skip_Log_Record;
```

```ada
   --  Disable logging only for the current processing request

   procedure Add_Listening
     (Web_Server     : in out HTTP;
      Host           : String;

pragma Ada_2012;

package AWS.Services.Dispatchers with Pure is

   --  Services on the Dispatcher tree are to help building big servers.
   --  Experiences shows that a lot of user's code is to check the value of a
   --  specific URI or request method to call the right callback that will
   --  handle the request. This code is a big "if/elsif/end if" that just hide
   --  the real job. A dispatcher is to replace this code. Currently there is
   --  five of them:
   --
   --  URI (AWS.Services.Dispatchers.URI)
   --     to dispatch to a callback depending of the resource name.
   --
   --  Method (AWS.Services.Dispatchers.Method)
   --     to dispatch to a callback depending of the request method.
   --
   --  Virtual_Host (AWS.Services.Dispatchers.Virtual_Host)
   --     to dispatch to a callback depending on the host name. This is known
   --     as virtual hosting and permit to have multiple servers on the same
   --     machine using the same port.
   --
   --  Transient_Pages (AWS.Services.Dispatchers.Transient_Pages)
   --     to handle transient pages, if the default user's callback returns
   --     404 this dispatcher checks if the requested resource is a transient
   --     page.
   --
```

```
   --  Timer (AWS.Services.Dispatchers.Timer)
   --     to dispatch to a specific callback depending on the current time.
   --
   --  Linker (AWS.Services.Dispatchers.Linker)
   --     to link two dispatchers together, if the first one retruns 404 tries
   --     the second one.

end AWS.Services.Dispatchers;

--  will return the Web pages found in the Web server directory. If directory
--  browsing is activated, it will be possible to browse directory content if
--  the requested resource is a directory. There is two specials files that
--  are recognized:
--
--     404.thtml            The Web page returned if the requested page is
--                          not found. This is a template with a single tag
--                          variable named PAGE. It will be replaced by the
--                          resource which was not found.
--
--                          Note that on Microsoft IE this page will be
--                          displayed only if the total page size is bigger
--                          than 512 bytes or it includes at least one
--                          image.
--
--     aws_directory.thtml  The template page used for directory browsing.
--                          See AWS.Services.Directory for a full description
--                          of this template usage.

--------------------------------------------------------------------------------

package AWS.Services.Split_Pages.Uniform.Alpha is

   --  Same as the uniform splitter, but builds in addition an alphabetical
   --  secondary index from a key field.
   --  For the references from the index to work, each line of the @@TABLE@@
   --  statement must include the following:
   --    <a name="@_TABLE_LINE_@>
   --  The alphabetical index will include one entry for empty fields, one
   --  entry for all fields that start with a digit, and one entry for each
   --  different initial letter.
   --  Note that leading spaces in the key field are ignored; this means that a
   --  key field containing only spaces is treated as an empty field.
   --  The key field is set by calling Set_Key. If no key is defined, or no
   --  corresponding association is found in Table, or the association is not a
   --  vector, Splitter_Error is raised.
   --  The key field must be sorted, and all values must be empty or start with
   --  a digit or letter (case ignored). Otherwise, Splitter_Error is raised.
   --
   --  Tags (in addition to those of the uniform splitter):
   --  S_HREFS_V     A vector tag containing a set of href to pages in the form
   --                <page>#<line>.
   --  S_INDEXES_V   A vector tag (synchronized with S_HREFS_V) containing
   --                "<>", "0..9", and the letters 'A' .. 'Z'
   --
   --  HREFS_V and INDEXES_V can be used to create an index to the generated
   --  pages. S_HREFS_V and S_INDEXES_V can be used to create a secondary
   --  alphabetical index that points directly to the corresponding element.

-------------------------------------------------------------------------------

--
--  This unit implements an API to send email messages. It is possible to send
--  simple email [RFC 821] and email with MIME attachments [RFC 2045 & 2049].
--
--  How to send an email:
--
--  1) Initialize a Server to send the messages.
--
--     Wanadoo : SMTP.Receiver := SMTP.Client.Initialize ("smtp.wanadoo.fr");
--
--     Optionally, request Authentication
--
--     Auth : aliased SMTP.Authentication.Credential :=
--             SMTP.Authentication.Plain.Initialize ("id", "password");
--
--     Wanadoo : SMTP.Receiver :=
--                SMTP.Client.Initialize
--                  ("smtp.wanadoo.fr", Credential => Auth'Access);
--
--  2) Send a message via the server.
--
--     Result : SMTP.Status;
--
--     SMTP.Client.Send
--        (Server  => Wanadoo,
--         From     => SMTP.E_Mail ("Pascal Obry", "pascal@obry.net"),
--         To       => SMTP.E_Mail
```

```ada
--                      ("Dmitriy Anisimkov", "anisimkov@ada-ru.org"),
--         Subject => "Latest Ada news",
--         Message => "now Ada can send SMTP mail!",
--         Status  => Result);

with AWS.Attachments;

   -- HTTPS --
```

```
   -----------

   function Check_Digest
     (D : Data; Password : String) return Messages.Status_Code;
   --  This function is used by the digest authentication to check if the
   --  client password and authentication parameters are correct.
   --  The password is not transferred between the client and the server,
   --  the server check that the client knows the right password using the
   --  MD5 checksum.
   --  Returns Messages.S200 in case of successful authentication,
   --  Messages.S400 in case of wrong authentication request
   --  (RFC 2617 3.2.2, 3.2.2.5),
   --  and Messages.S401 in case of authentication error.

   function Check_Digest (D : Data; Password : String) return Boolean;
   --  The same as above, but do not distinguish wrong requests and
   --  authentication errors.

   function Authorization_Mode    (D : Data) return Authorization_Type
     with Inline;
   --  Returns the type of the "Authorization:" parameter

   function Authorization_Name    (D : Data) return String with Inline;
   --  Returns "username" value in the "Authorization:" parameter

   function Authorization_URI     (D : Data) return String with Inline;
   --  Returns "uri" value in the "Authorization:" parameter
   --  Note, it could differ from HTTP URI field, for example Mozilla browser
   --  places http parameters to the authorization uri field.

   function Authorization_Password (D : Data) return String with Inline;
   --  Returns "password" value in the "Authorization:" parameter

   function Authorization_Realm   (D : Data) return String with Inline;
   --  Returns "realm" value in the "Authorization:" parameter

   function Authorization_Nonce   (D : Data) return String with Inline;
   --  Returns "nonce" value in the "Authorization:" parameter

   function Authorization_NC      (D : Data) return String with Inline;
   --  Returns "nc" value in the "Authorization:" parameter

   function Authorization_CNonce  (D : Data) return String with Inline;
   --  Returns "cnonce" value in the "Authorization:" parameter

   function Authorization_QOP     (D : Data) return String with Inline;
   --  Retruns "qop" value in the "Authorization:" parameter

   function Authorization_Response (D : Data) return String with Inline;
   --  Returns "response" value in the "Authorization:" parameter

   function Authorization_Tail    (D : Data) return String with Inline;
   --  Returns precalculated part of digest composed of
   --  Nonce, NC, CNonce, QOP, Method, URI authorization fields.
   --  To build a full authorization response you can use:
   --
   --  MD5.Digest
   --     (MD5.Digest (Username & ':' & Realm & ':' & Password)
```

```
   --        & Authorization_Tail);
   --
   --   This method can be used to avoid sending a password over the network.

--------------------------------------------------------------------------------

pragma Ada_2012;

--  This package contains all SOAP types supported by this implementation.
--  Here are some notes about adding support for a new SOAP type (not a
--  container) and the corresponding WSDL support:
--
--  1. Add new type derived from scalar in this package. Implements all
--     inherited routines (Image, XML_Image and XML_Type). Implements also
--     a constructor for this new type and a routine named V to get the
--     value as an Ada type.
--
--  2. In SOAP.Parameters add corresponding Get routine.
--
--  3. In SOAP.WSDL, add the new type name in Parameter_Type.
--
--  4. Add support for this new type in all SOAP.WSDL routines. All routines
--     are using a case statement to be sure that it won't compile without
--     fixing it first. For obvious reasons, only SOAP.WSDL.To_Type and
--     SOAP.WSDL.From_Ada are not using a case statement, be sure to do the
--     right Change There.
--
--  5. Finaly add support for this type in SOAP.Message.XML. Add this type
--     into Type_State, write the corresponding parse procedure and fill entry
--     into Handlers. Again after adding the proper type into Type_State the
--     compiler will issue errors where changes are needed.
